A possible way in which a simple 'two-word' hypercycle might be realised in molecular terms is shown in Fig. 2. (Eigen and Schuster would not insist on this particular realisation; it is intended only to show the kind of thing they have in mind). It is necessary to describe a cycle in some detail, so as to be able to discuss the difficulty which arises in explaining the further evolution of such cycles. I_1 and I_2 would remain — GOD only, or THE only, if short words replicate faster.
are two RNA quasi-species. Both the + and — strands must be good replicators. RNA molecules have a phenotype, because they fold up, and folding patterns affect both survival (resistance to hydrolysis) and replication rate. Since both + and - strands must replicate, they are likely to have similar folding patterns. Further, I_1 and I_2 may be descendants of the same ancestral quasi-species, in which case they will resemble one another.

In this particular realisation, the

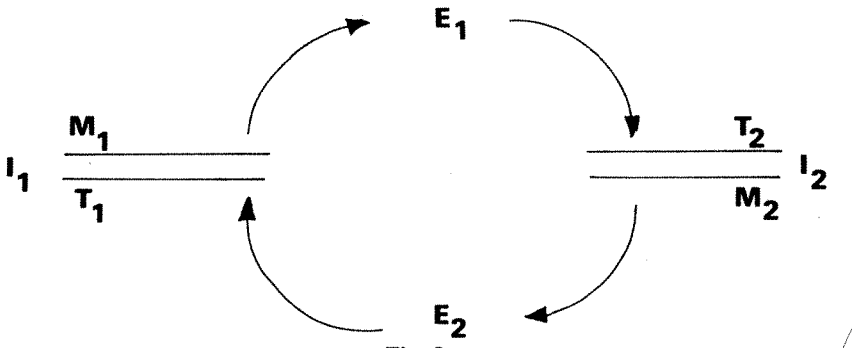

Fig. 2

— strands T_1 and T_2 are supposed to be 'adapters' or precursors of tRNA, coupling with specific amino acids, and having an anticodon loop. The + strands M_1 and M_2 are 'messengers', composed of only two kinds of codon, and coding for two proteins E_1 and E_2 which act as replicases for I_2 and I_1 respectively. Thus the model assumes that some kind of translation is possible without synthetases or ribosomes, and that the code is arbitrary from the start (that is, that there is no chemical constraint on which triplet codes for which amino acid). It is not an essential feature of the argument that messenger and transfer molecules be the + and — strands of the same quasi-species, but if they were not, then a hypercycle of more than two elements would be needed.

One difficulty in conceiving how such a cycle might arise is that it requires that each of two 'messengers' (or of more than two in the case of a longer cycle) should programme a replicase for the other: Eigen and Schuster argue that this becomes less implausible if it is remembered that I_1 and I_2 may be descended from members of the same molecular quasi-species. Initially, the members of a quasi-species would be sufficiently alike to share the same replicase. Hypercyclic organisation could then arise by the gradual differentiation of a single quasi-species into two or more.

I now digress to give the authors' views on the origin of the code. They argue that primitive RNA molecules must have been G–C rich (for reasons already mentioned). Further, in the absence of ribosomes the message must have been one which could only be read 'in frame' (Crick *et al. Origins of Life*, 7, 389; 1976). These two conditions imply that the earliest messages consisted of strings either of GNC codons or CNG codons, where N stands for any base. The authors use an argument based on wobble to prefer the former codon type. Hence, from arguments based on the stability, replication and translation of nucleic acids, they conclude that the first two codons were GGC and GCC, followed by GAC and GUC. This conclusion agrees nicely with the likely abundances of amino acids in the primitive oceans. By far the most abundant amino acids in simulated prebiotic synthesis (reviewed by Miller and Orgel, *The Origins of Life on Earth*, Prentice-Hall, 1973) are glycine and alanine (today coded by GGC and GCC), the next commonest being aspartic acid (GAC) and valine (GUC).

Returning to the main theme, the following question arises. Given that a hypercycle ensures the accurate replication of a larger total quantity of information, how will it evolve further? Consider the particular realisation in Fig. 2. There are three kinds of mutation which might occur in I_1 (and a similar set in I_2):

(1) Mutations making I_1 better (or worse) at replicating, for example by becoming a better target for E_2. (I_1 might also become a better target for E_1; if this process went too far the hypercycle would be disrupted).

(2) Mutations making E_1 a better (or worse) replicator of I_2.

(3) Mutations making T_1 a better adapter.

If there is not compartmentalisation, only mutations of type (1) would be incorporated by selection. Each quasi-species in the hypercycle would evolve independently. There would be no selection favouring mutations of types (2) and (3), although such mutations would be needed before the speed and accuracy of replication would improve sufficiently to permit the genetic information to be united in a single 'chromosome'. There is a natural analogy here to an ecosystem. Imagine an ecosystem consisting of grass, antelopes and lions. The more grass there is, the more rapid is the multiplication of antelopes. Similarly, antelopes encourage the multiplication of lions, and (by some stretch of the imagination) lions, by fertilising the ground, encourage the growth of grass. The point of the analogy is this. Natural selection will favour mutations in grass which increase the fitness of individual grass plants, but will not favour changes in grass making it more edible to antelopes.

How then can a hypercycle evolve characteristics which favour the growth of the cycle as a whole, rather than merely its constituent parts? So long as there is no compartmentalisation, it cannot. For natural selection to act, there must be individuals. In the present context, this seems to require that the compartments of a hypercycle be enclosed in a membrane to form a proto-cell. If these proto-cells grew and divided – by some kind of budding or fission – at a rate which increased with the growth rate of the enclosed hypercycle, then selection would favour mutations making the hypercycle more efficient. In the example of Fig. 2, mutations of types (2) and (3) would be favoured.

Clearly, these papers raise more problems than they solve. Their merit is that they put in sharp terms the problem raised by the relatively inaccurate replication of nucleic acids, and, in the hypercycle, they suggest a way in which a relatively complex structure could be replicated despite this inaccuracy. □

More twists and turns to recombination

from a Correspondent

CURRENT understanding of the molecular basis of homologous DNA recombination has evolved from analyses of the progeny of fungal and bacterial genetical crosses, the isolation of mutants deficient in some or all of the steps, electron microscopy of DNA intermediates generated *in vivo* or *in vitro* and most recently from biochemical studies of the proteins involved acting on specific substrates. The integration and transposition of IS elements, transposons and bacteriophage Mu into bacterial chromosomes has also stimulated interest in non-homologous recombination. The five EMBO recombination workshops have reflected this evolution and the latest one contained a fascinating mixture*.

Genetical analysis of fungal tetrads and octads provided support for the Meselson–Radding recombination model, which proposes initiation by invasion of a single DNA strand from one duplex into a second one, resulting in asymmetrical hybrid DNA. Symmetrical hybrid DNA can then be generated by the Siegel–Alberts isomerisation. The pattern of gene conversion and postmeiotic segregation at the b_2 locus of *Ascobolus* is consistent with asymmetrical initiation of recombination from a preferred site outside the locus followed by a transition to a symmetrical structure, with the probability of repair of mismatched bases in the hybrid DNA decreasing with increasing distance from the initiation site (J. L. Rossignol, Université de Paris-Sud, Orsay). The positions of strand crossing-over and hybrid DNA during recombination at the *arg4* locus of yeast is, however, contrary to the model's predictions and evidence for symmetrical hybrid in yeast is lacking (S. Fogel, University of California, Berkeley). Although the direction of correction can be random in fungi, there was agreement that correction to the invading strand information is strongly preferred in yeast (Fogel; P. Hastings, University of

*The fifth EMBO Workshop on DNA Recombination, was held at Nethybridge, Scotland from 25-30 June, 1979.

0028-0836/79/320446-01$01.00

©Macmillan Journals Ltd 1979

Edmonton, Edmonton) and in *Sordaria*, correction may influence the likelihood of nearby cross-overs (H. Sang, Harvard University).

Repair of mismatched bases when artificial heteroduplex λ DNA molecules transfect wild-type hosts was explored (M. Radman, Université Libre de Bruxelles, Brussels). Correction occurs on the unmethylated strand, an observation of importance for correction of non-complementary bases inserted during DNA replication when parental and nascent strands are differentially methylated. During replication in *dam* mutants (adenine methylation blocked), correction can occur on both strands, perhaps leading to overlapping recombinogenic excision tracts, explaining the hyper-Rec phenotype of these mutants. Transfection of the heteroduplexes into mutator *mut* H, L and S hosts results in the loss of preferential correction. Furthermore, λ crosses under non-replicating conditions revealed that crossing-over between widely spaced markers was similar in wild-type and *mut*S hosts, whereas mismatch repair in the λ *P* gene was reduced 10-fold in the latter host, suggesting that mismatch repair is specifically blocked in these mutator strains.

Chi mutations in λ confer large plaque size on *red*$^-\gamma^-$ mutants of λ infecting *rec*A proficient hosts and also stimulate recombination in their vicinity in the λ genome. They also occur naturally in λ, *Escherichia coli* and yeast. It was suggested that the basis of their strong directionality of action might lie in the directional packaging of λ DNA and that during attempted packaging, they might resolve recombination intermediates, leading to exclusion of one of the possible products. From limited sequence data, the number of nucleotides common to all chi sequences is not yet certain. It could be as high as 23, which would not be expected to occur randomly at the frequency observed in yeast, suggesting the exciting possibility that they might be universal recombinators (F. Stahl, University of Oregon, Eugene).

The development of *in vitro* recombination systems, retarded by the lack of a versatile assay, makes the purification and characterisation of the proteins involved possible. A rapid filter-binding assay has resolved several peaks of DNA circle fusion activity after DEAE chromatography of *E. coli* extracts and one has been purified further. It is, however, present in equal amounts in both *rec*A$^-$ and wild-type extracts and so its relationship to *rec*A dependent recombination *in vivo* is obscure (D. Dressler, Harvard University). A different approach assays T7 DNA recombination *in vitro* and two pathways have been delineated. In one, purified gene 6 exonuclease catalyses recombination between two DNA duplexes or between one duplex and single strands of another. The renaturing activity of the T7 single-stranded DNA binding protein is also required (P. Sadowski, University of Toronto).

The *rec*A protein of *E. coli* is the subject of intense study because the cloning of the gene enables large amounts of the protein to be purified. It is a DNA-dependent ATPase, unwinds DNA and catalyses the insertion of homologous linear single-stranded DNA into superhelical or linear duplex DNA to form D-loops, a putative early stage in recombination (C. Radding, Yale University). On the basis of studies using ATP and a non-hydrolysable analogue, the mechanism proposed was ATP-dependent binding to homologous single strands (without ATP hydrolysis), the resulting complex unwinding the duplex DNA and annealing the single strands into the duplex, accompanied by ATP hydrolysis. Perhaps similar success will follow the cloning of the *rec*F gene (A. J. Clarke, University of California, Berkeley). Recombination promoted by the λ *int* gene, which ensures the integration of λ DNA into a specific site in the host chromosome, can also be accomplished *in vitro*. The purified *int* protein has now been shown to be a topoisomerase (H. Nash, National Institutes of Health, Bethesda). It resembles eukaryotic topoisomerases and does not require attachment sites in its substrate for this activity, but its preferred binding to the phage attachment site and left attachment site may focus its activity at the specific region needed for λ integration and excision. Thus, whereas it was envisaged that recombination would require several enzymes acting sequentially, the biochemistry suggests that rather simple, but multi-functional ones can accomplish at least some initial events on their own.

The integration and transposition of IS sequences, transposons and bacteriophage Mu involves specialised or non-homologous recombination, and transposition is non-reciprocal because they are inserted into a recipient without their loss from the donor. Thus DNA synthesis is an integral part of transposition. Partial deletions in Tn*3* were used to analyse transposon functions required for transposition (D. Sherratt, University of Sussex). Some deletions blocked transposition at an intermediate stage where a Tn*3*-containing plasmid was physically linked to a recipient plasmid. In some cases such intermediates were resolved by the host *rec*A system which was, however, less efficient than the transposon's own system. A sequence within 250 base pairs of a gene coding for a 19,000 molecular weight protein was also mapped which is required in *cis* to resolve cointegrates or Tn*3* dimers in a plasmid. A search for *E.coli* mutants reducing IS*1*-mediated deletion formation in the *gal* operon revealed a trans-acting locus named *del* (P. Nevers, University of Freiburg). From further studies, it was concluded that *del*$^+$ might be a natural IS*1* sequence linked to a strong promotor acting in trans to boost IS*1* functions at a second insertion site in the *gal* operon.

Bacteriophage Mu shares many properties with transposons, such as a requirement for replication to transfer Mu from one site to another (A. Bukhari, Cold Spring Habor Laboratory, New York). Also Mu can transpose from one plasmid to another equally efficiently in *rec*A$^+$ and *rec*A$^-$ hosts, but in the latter, cointegrates are detected which can be resolved by the *rec*A$^+$ system. Two Mu deletion mutants also form cointegrates, but the one with deleted early genes is unable to transpose into the host chromosome (D. Leach, University of Sussex). When Mu is induced, the *G* region of about 50% of the progeny is inverted, preventing growth of Mu on *E. coli*. This puzzle has been resolved because this loss of infectivity is matched by a gain in ability to infect other bacteria. *G* inversion apparently activates different *S* genes, coding for host specific phage tail fibres, by way of a promotor at the left of *G*. Inversion also increased read-through of a flanking gene *mom* which antagonises host-specific modification of Mu DNA so that phage with a new host range are less likely to have their DNA restricted.

Transposon-like sequences may also exist in yeast. The *his*4-912 mutation maps outside structural genes, is polar but is not a nonsense, frameshift or deletion and revertants are unstable and cause chromosomal rearrangements. Restriction fragments containing the region from *his*4-912, a revertant and wild-type decrease in length in that order, the revertant being longer than the wild-type by 250 base pairs, a sequence found in many yeast restriction fragments. It was suggested that *his*4-912 contains a transposable element in the promotor which is excised in the revertant leaving a 250 base pair terminal repeat (G. Roeder, University of Toronto). The 'Cassette Model' for control of the mating type in yeast is also consistent with a transposition-like mechanism. Cloning of the α and A mating type alleles indicates that the former is 200 base pairs longer, but the degree of internal homology between them remains to be determined (A. Klar, Cold Spring Harbor Laboratory).

The possible involvement of recombination in carcinogenesis was proposed by Radman and A. Kinsella. TPA, a strong promotor of carcinogenesis, causes a large increase in sister chromatid exchanges in cultured CHO cells. They propose that carcinogenesis is initiated by mutations which remain silent because of the presence of intact DNA on the homologous chromosome. If recombination occurs, perhaps stimulated by TPA, there is an opportunity for the loss of the wild-type gene, permitting expression of the carcinogenic mutation. Their proposal was strengthened by the finding that the anti-tumour agent antipain, prevents sister chromatid exchange. □

Structure and control of phosphorylase

from C.C.F. Blake

IT is perhaps not really surprising that the promise that X-ray crystallography can make a vital contribution to the understanding of enzyme regulation, by being able to define the various structural states through which the activities of control enzymes are regulated, is taking a long time to be completely fulfilled. The enzymes by their very nature are large, their conformational states can be various, and can differ from one another to such an extent that a number of crystal forms may have to be analysed separately (if they can be obtained at all). Of the four regulatory enzymes whose X-ray study is well advanced: glycogen phosphorylase, hexokinase, phosphofructokinase and glyceraldehyde phosphate dehydrogenase (all members of the glycolytic pathway), phosphorylase is under the most elaborate control. This suggests that the analysis of its structural and regulatory properties now under way by Fletterick and Madsen in Edmonton, and Johnson in Oxford will be especially valuable in providing information on the regulation of metabolism.

Glycogen phosphorylase is, of course, the classic example of hormonal control of a metabolic enzyme through the mediation of the adenyl cyclase system. Phosphorylase *b* is converted to phosphorylase *a* by the phosphorylation of Ser 14 by a specific kinase; a reaction that is reversed by a specific phosphatase. This hormonal regulation is linked to further control by the levels of a number of metabolites, including AMP, ATP and glucose-6-phosphate. Phosphorylase *b* requires AMP for activity and is allosterically inhibited by ATP and glucose-6-phosphate. In resting muscle the levels of these metabolites are such that this form of the enzyme is inactive. The conversion of the *b*-form to the *a*-form results in an enzyme that no longer requires AMP for activity and is not subject to allosteric inhibition. However, it is strongly inhibited by glucose, for which it is regarded as a receptor in the liver, and which promotes the conversion of the *a*-form to the *b*-form by the phosphatase. In addition phosphorylase is in intimate physical association with the glycogen particles, and this association also seems to affect the enzymic activity.

X-ray studies are being carried out on crystals of phosphorylase *b* grown in the presence of its activator IMP at 3 Å resolution (Johnson *et al. Proc. 11th FEBS Mtg.* **42**, 185; 1978; Weber *et al. Nature*, **274**, 288; 1978) and of phosphorylase *a* in the presence of its inhibitor glucose at 3 Å resolution (Fletterick *et al. J. biol. Chem.* **251**, 6142; 1976) which have now been extended to 2.5 Å resolution (Sprang & Fletterick, *J. molec. Biol.* **131**, *523;* 1979). It was extremely valuable that the complete sequence of the 841 residues of rabbit muscle phosphorylase was determined by Neurath's group (Titani *et al. Proc. natn. Acad. Sci. U.S.A.* **74**, 4762; 1977) at the time when the electron density maps were being interpreted. The 97,400 molecular weight subunit of phosphorylase has its polypeptide chain organised largely into alternating α- and β- structures, like all the other glycolytic enzymes whose structures are known. The folding of the polypeptide chain divides the large subunit into three domains: an N-terminal domain of about 320 residues, a central domain of 160 residues, and a C-terminal domain of about 360 residues. These three domains are located at the apices of a roughly equilateral triangle giving the subunit a compact shape. The interface of the functional dimers in the crystals is formed by the N-terminal domains and includes two large projections, known as the 'tower' and the 'cap' that extend beyond the molecular two-fold symmetry axis to make extensive contacts with the other subunit. A most striking feature of the subunit is the location of the active site at the bottom of a deep, narrow cavity near the centre of the subunit at the point where the three domains come together. The pyridoxal phosphate, whose presence was so long a mystery, is bound as a Schiff's base to Lys 679 close to the active site in apparent confirmation of proposals that it is directly involved in the catalytic process. In phosphorylase *a*, the glucose inhibitor is bound in the active site.

Rather surprisingly the crystals of phosphorylase *a* and *b* are closely isomorphous, suggesting no large structural difference between them. Unfortunately no detailed comparisons of the two structures have yet been made, but it seems that a major difference lies in the N-terminal region which in the *b*-form is disordered, but becomes ordered in the *a*-form because the phosphate group attached to Ser 14 makes an ionic interaction with Arg 69 located on the N-terminal helix. Soaking experiments with substrates, activators and inhibitors have revealed further binding sites (Kasvisky *et al. J. biol. Chem.* **253**, 1290, 3343; 1978; Johnson *et al.* unpublished). The allosteric activator site lies on the N-terminal domain at the subunit interface. AMP and ATP located in this site make contact with residues from both subunits. Maltotriose and maltoheptose bind at a site on the central domain, which has consequently been termed the glycogen storage domain, but do not seem to bind at the active site. Finally, AMP, ATP and the inhibitors caffeine and inosine, bind near the active site in a position that probably marks the allosteric inhibitor site.

Despite the success in locating these five ligand binding sites, the only evidence for associated conformational change has been obtained from crystals of phosphorylase *a* in the presence of the virtual substrate, 5-thio-α-D-glucopyranosyl phosphate, and maltoheptose (Madsen *et al. J. biol. Chem.* **253**, 9097; 1978). To prevent the disintegration of the crystals that usually accompanies attempts to bind substrate, they were lightly cross-linked with glutaraldehyde and allowed to anneal after the addition of the substrate analogue. Difference maps at low resolution revealed that the segments in the N-terminal half of the molecule had undergone conformational change, possibly representative of the R → T transition. The most intriguing aspect of these conformational changes is that they appear to link together the five major ligand binding sites. These structural changes seem to bear obvious relationships to the known homotropic and heterotropic cooperativities of the enzyme.

The work on phosphorylase is an exemplar of X-ray studies on enzymes, regulatory or not, both in its successes and difficulties. As is usual the structural results are clear, and revealing. The division of the molecule into three domains of specialised function is characteristic, as is the location of the active site at the triple domain interface. The domain/subunit geometry lays the groundplan for regulation by defining, broadly, the structural pathways of communication between the various control sites and the active sites. However, as is also usual, the definition of function, that is how the communication actually works, seems more problematic even though in this case some low resolution results have been obtained with phosphorylase *a*. This is because the structural changes induced by ligand binding may be partly, or wholly, inhibited by the crystal lattice. Ideally separate structural analyses of crystals representing each stable structural state are required, but that may not be possible because certain states may not crystallise. Function is always the most difficult aspect of X-ray studies, and one that requires much further effort. □

C.C.F. Blake is in the Laboratory of Molecular Biophysics, Department of Zoology, University of Oxford.

Erratum

IN the article 'The Oceanography of Fjords (*News and Views* **280**, 273; 1979) the figure legend is incorrect. The upper figure represents the laboratory simulation and the lower the tidally-generated flow in a fjord, and not as stated.

Theoretical difficulties with the binary pulsar?

from Malcolm MacCallum

THE agreement of the rate of change of period of the binary pulsar with the usual quadrupole formula for gravitational radiation, reported by J. H. Taylor, L. A. Fowler, and P. M. McCulloch (*Nature* **277**, 437; 1979), has been hailed as a triumph for general relativity. Unfortunately it has been known to specialists for some time that the theoretical predictions are themselves open to question.

J. Ehlers, A. Rosenblum, J. N. Goldberg and P. Havas drew attention to the unsatisfactory nature of all existing derivations of the formulae in an article in the *Astrophysical Journal* in 1976 (**208**, L77). Concerning these arguments, Taylor *et al.* remark that "our data suggest that any such inaccuracy is not very large", but there is of course the more intriguing possibility that the observations disagree with the correct general-relativistic formula. Indeed, what some specialists fear most is that the usual formula will prove correct to better than 10%, with the consequence that any future objections to non-rigorous arguments in relativistic astrophysics and cosmology will be dismissed as merely pedantic quibbles.

In deriving the standard formula, L. D. Landau and E. M. Lifschitz (in *The Classical Theory of Fields* third edition, Pergamon, 1971) wrote "In principle, all the calculations are completely analogous to those which we carried out for electromagnetic waves." It is this analogy which has given the quadrupole formula its strong intuitive appeal to physicists, but it also emphasises the underlying reasons for some of the experts' doubts, namely that it uses an essentially linear approximation in a flat space-time background when the full theory is non-linear and uses curved spaces.

Since 1976 renewed efforts have been made to reach an agreed alternative to (or confirmation of ?) the usual formula, based on more sophisticated approximations, and the Gregynog meeting* provided an opportunity to review progress. Some of the most illuminating results reported arose from model calculations using scaler waves in one dimension (whose relevance is accentuated by a recent preprint from J. M. Stewart (University of Cambridge) showing that perturbations of algebraically special space-times — which include most of the physically interesting cases — can be represented in terms of scaler potentials).

At great distances from the sources, the field is usually assumed to propagate along flat space light rays and to be expandable in inverse powers of the radial distance r. Stewart, speaking about definitions of mass at infinity, reminded the audience that, however small the mass involved, light rays in the field of a spherical body (a Schwarzschild metric) would diverge logarithmically from those of the corresponding flat space. M. Walker (Max-Planck-Institute, Munich) reported an example in which logarithmic terms appear in the field in the far past.

One way of relating the field to the sources is through a retarded Green's function integral. In relativity, however, such retarded solutions are not simply related to natural choices of boundary condition, such as 'no incoming radiation in the far past' or 'only outgoing radiation in the far future'. Walker gave an example in which the retarded solution involved incoming radiation in the far past. B. Schmidt (Max-Planck-Institute, Munich) presented a string and spring example in which the amount of incoming radiation affected the damping rate, and speculated, amusingly, that the binary pulsar measurements might mean only that if general relativity is true, the pulsar is receiving no incoming radiation. Schutz proposed avoiding the boundary conditions by assuming that at an initial instant the field external to the system, being unknown, should be taken to be zero — the average of all possible values.

The dynamics of the source has to take account of the reaction from the field. Schutz showed that in his approach the usual radiation reaction expression acquired an extra term, which he related to the need to compensate for coordinate choice effects. More detailed examinations of the internal dynamics of the sources usually follow one of two approximation schemes.

The first of these is the 'fast motion' approximation. D. Christodoulou (Max-Planck-Institute, Munich) reported on some rigorous estimates of errors in this scheme. A. Rosenblum (Temple University, Philadelphia) reported that the well-known discrepant result of Havas and Goldberg (that two bodies in a binary system spiral away from, not towards, each other) was due to neglect of non-linear terms comparable with those retained, and presented his own scattering calculations, which gave about double the result predicted by the quadrupole formula. He hopes to extend these calculations to bound systems.

The second method is the 'slow motion' technique, which involves expansion in powers of a small parameter e, essentially the ratio of a characteristic velocity in the system to the velocity of light. The calculations introduce terms in er, and are therefore valid only in a limited region. The boundary conditions for the slow motion approximation should be supplied by an outer, wave zone, solution, which itself must use the light rays of the curved space, and not a flat space approximation. Both Dixon and J. L. Anderson (Stevens Institute, Hoboken, New Jersey) have carried out model calculations of this type, joining the inner and outer regions by the method of matched asymptotic expansions. This method was introduced to relativity by W.J. Burke (*J. Math. Phys.* **12**, 401; 1971), but has been familiar in other contexts for some time, and is even known to be rigorous in certain limited circumstances. Because their calculations differed in detail, Dixon and Anderson, although in broad agreement, emphasised different aspects of the results.

Dixon's model calculation showed, contrary to some expectations, that slow motion expansions can include effects arising from tail terms of a retarded Green's function (crudely, effects propagating at a speed less than that of light), and that radiative effects can appear in even as well as odd orders in the expansion. Both authors found that the matching introduced terms in the inner region logarithmic in e. Anderson noted that approximations good for one feature may be bad for another (in his example, the damping and phase respectively), though I understand that at the subsequent Dublin meeting ('Current Problems in General Relativity', 2-6 July, 1979) P. Parker (Syracuse University) suggested that this could be overcome using results by Hörmander (*Acta Math.* **127**, 79; 1971).

The problem of what to approximate recurred in a final discussion excellently led by Stewart. It was agreed that intermediate concepts like energy (awkward to define in the full theory) and radiation reaction force should be avoided if possible, and attention focused on directly measurable quantities (like the binary pulsar period changes). Care would be needed to avoid tailoring approximations to produce the 'right' results, so that as many observable effects as possible should be included.

Stewart concluded the meeting by announcing a competition for a model problem, with an unambiguous numerical solution, which could act as a testbed for the different approximation schemes. It should have as many features of the full problem as possible, for example, non-linear waves, retarded coupling to a source oscillator, and back-reaction on the source. Perhaps when such a problem has been found, and solved, we will know how to tackle the binary pulsar question. Then we can decide whether the observed behaviour presents difficulties for the theory, or whether the present doubts will prove only 'theoretical' in the worse sense.

Malcolm MacCallum is a lecturer in the Department of Applied Mathematics, Queen Mary College, London.

*The third Gregynog Relativity Workshop was held at Gregynog, Newtown, Wales, on 25-28 June, 1979, under the title 'Gravitational Radiation Theory'. The organisers were B. Schutz (University College, Cardiff), G. Dixon (Churchill College, Cambridge) and M. Walker (Max-Planck-Institute, Munich).

Minding the psi's and q's

from Roger Cashmore

THE European Physical Society's International Conference on High Energy Physics* was held in Geneva this year — the 25th anniversary of CERN. Much of the data presented originated from accelerators within Europe, from the CERN SPS and ISR together with a substantial contribution from the new e^+e^- storage ring PETRA at DESY.

Much of the conference was devoted to reports on the physics of both the new quarks, (charm and bottom — c,b) and the old quarks (up, down and strange — u,d,s) as well as searches for the expected quark (top — t). First the charm quark. Within the charmonium model of the $c\bar{c}$ meson states, the claimed pseudoscalar states ($^1S_0$ states), the κ ($\sim$2830) and κ ($\sim$3450) have long been a problem. They possessed masses, widths and M1 electromagnetic transition rates in conflict with predictions from charmonium. In the crystal ball experiment at SPEAR, an experiment particularly designed to study the electromagnetic transitions from the ψ' and ψ mesons using high resolution NaI crystals, no evidence has been found for these states at the claimed mass values, although all of the other intermediate states have been observed (the $^3P_{0,1,2}$ states — the $\chi(3400)$, $\chi(3510)$ and $\chi(3550)$). Thus the embarrassing problem of having states of the grossly wrong properties has been removed but replaced by the lesser problem of the whereabouts of these mesons, vital in the $c\bar{c}$ picture. In a separate experiment at SPEAR, using the Mark II detector, data has been taken on the D^0 and $\bar{D}^0$ mesons at the ψ'' (3772), a copious source of these particles. With the high statistics obtained the first observations of the Cabbibo suppressed $D \to \pi\pi$ and $K\bar{K}$ decays have been made which are consistent with 6 quark extensions of the GIM model of incorporating new quarks into the weak and electromagnetic gauge theories.

Until this conference evidence for charmed baryons has been scant, the only observations being in neutrino experiments and one photoproduction experiment. Three experiments from the ISR reported the observation of narrow hadronic states consistent with the earlier observations. These states have appreciable diffractive production cross sections ($\sigma.B \sim 1\mu b$, where B is the decay mode branching fraction) while the more prominent decay mode of the lightest of these baryons, the Λ_c^+ ($\sim$2255) appears to be to $K^-p\pi^+$ although the $\Lambda^0\pi^+\pi^+\pi^-$ decay is observed. This conclusion is supported by evidence from SPEAR that the $p+\bar{p}$ yield increases more dramatically than the $\Lambda+\bar{\Lambda}$ yield in the vicinity of 5.0 GeV, the region where charmed baryon production is expected to occur.

*Held on 27 June-4 July.

Probably the most exciting prospect at the conference was the suggestion of a meson containing a bottom (b) quark. The b quark is expected to decay preferentially to a c quark and it has been surmised that this c quark might appear a fraction of the time within a ψ meson together with at least one 'strange' particle. A group (Indiana/Imperial College/Saclay/Southampton collaboration) studying ψ production in $\sim$150 GeV π^-p collisions at the CERN SPS looked at the $\psi K\pi$ final states and discovered an excess of events ($\sim$4 standard deviations) concentrated in a single 40 MeV bin at a mass of $\sim$5.3 GeV. From a knowledge of the Υ state, assumed to be a $b\bar{b}$ meson, the mass of a meson containing a bottom quark can be estimated and falls in this vicinity. Clearly further experimental results are eagerly awaited in the hope of confirming this exciting possibility.

Finally, an expected new quark, the t quark, has not yet been revealed in e^+e^- annihilation experiments at PETRA. Thus the mass of this quark must be greater than 13.5 GeV and means that the new accelerator must be stretched to its present limit of 16 GeV in the hope of discovering it.

Nearly all known mesons and baryons can be accommodated in models of hadrons in which mesons are $q\bar{q}$ states and baryons are qqq states, leading to the puzzle of the absence of resonances composed of greater numbers of quarks, for example $q\bar{q}q\bar{q}$ or $qqqq\bar{q}$. A few narrow structures observed in $\bar{p}p$ annihilations had been the best candidates for such states but unfortunately in a recent $\bar{p}p$ experiment at Brookhaven National Laboratory no evidence was found for the existence of one of the best of these candidates, the S(1935). Thus the puzzle remains as one of the most important questions of hadron physics.

The problem of permanently confining quarks within hadrons has apparently yet to be solved despite the tremendous amount of theoretical effort directed towards QCD (quantum chromodynamics — the theory of coloured quark and gluon interactions), a possible theory of the strong interaction. The experimental evidence for jets of particles, the remains of original quarks, was beautifully demonstrated in the new results from PETRA. However the evidence for the gluons which are essential in this picture remains tentative. Data presented on the decay of the Υ (9.45) is clearly best fitted with a model which describes its decay by way of three gluons, while in the high energy e^+e^- annihilation the evidence for a third jet (a gluon bremsstrahlung from one of the quarks) was tantalising. The existence of this effect together with a quantitative confirmation of the QCD predictions will only be obtained with the acquisition of much more data during the coming year. Results were also presented on the variation of the moments of the structure functions in deep inelastic νN and μN scattering, the 'classic' testing ground of QCD to date. Once again these were consistent with the predictions of QCD but fall short of a definitive proof, since other explanations are possible.

Results from all the high energy physics experiments studying the weak neutral current are now consistent with a value of $\sin^2\theta_w = 0.23$, the one parameter in the Weinberg-Salam model for a gauge theory of the weak and electromagnetic interactions. The only area in which there is any conflict with this value lies in atomic physics experiments studying parity violation in thallium and bismuth atoms. However here there are direct conflicts between the various experiments and a further sequence of experiments is clearly required before this situation is resolved.

There remains the unification of the weak, electromagnetic and strong interactions. The currently most popular models imply a 'desert' from the mass region of the W and Z intermediate bosons ($\sim$100 GeV) to the mass at which the various interactions have a similar strength — the grand unification mass ($\sim 10^{15}$ GeV). However A. Salam, in his summary, pointed out that this 'desert' was model-dependent and indeed other models would lead to a proliferation of particles in this region — only experiment will reveal the correct path. This represented a clear challenge to the experimental high energy physicists to understand better the properties of the particles of today and furthermore to achieve these higher energies as soon as possible with the accelerators of the future, the $\bar{p}p$ collider at CERN and, one hopes, LEP. □

Naming names

IN a paper published in this issue of *Nature* (page 468) V. Bennett and P.J. Stenbuck describe how a red cell membrane protein is linked to the cytoskeletal spectrin through the membrane Band 2.1 protein. Bennett and Stenbuck have recently rechristened Band 2.1 protein ankyrin (Greek, anchor). But beware. The self-same protein has, by others, been rechristened nexin (Latin, to bind) and syndein (Greek, to bind). Perplexingly, the work that led to all three christenings was initiated in one laboratory, that of Professor D. Branton at Harvard.

This etymological discordance is hardly edifying. Perhaps the younger generation should devote less time to scouring dictionaries and reflect instead on other traditions. After all there was a time when the leader of an expedition could expect to have his (or even her) name enshrined in any new species discovered by juniors.

So, by way of revitalising an old tradition, I hereby propose that the names ankyrin, nexin and syndein be cast aside in favour of brantonin (from, if you must, the words branch — a subdivision — and ton — a large quantity). International Commissions on Nomenclature please note. **P.N.**

Evidence for the quantum nature of light

D. F. Walls
Department of Physics, University of Waikato, Hamilton, New Zealand

A unique property predicted by the quantum theory of light is the phenomenon of photon antibunching. Recent theoretical predictions and experimental observations of photon antibunching in resonance fluorescence from a two-level atom are reviewed.

THE advent of photon correlation experiments, as pioneered by Hanbury-Brown and Twist[1], began a new era in the field of optics. The experiments of classical optics involved a measurement of the first-order correlation function of the electromagnetic field and as such involved only the interference between the probability amplitudes of a single photon. Phenomena such as diffraction, Young's interference experiment and spectral measurements may be categorised as being in the domain of one photon or linear optics. Photon correlation experiments represent a fundamental deviation from these experiments as they involve the interference between different photons and as such are in the realm of nonlinear optics. The quantum-mechanical interpretation of the Hanbury-Brown Twiss effect was given by Glauber[2]. However, adequate explanations of the Hanbury-Brown Twiss effect and related photon correlation experiments have been given which invoke a classical description of a fluctuating electromagnetic field. However, Glauber[2] pointed out that photon correlation experiments offer the possibility of observing a uniquely quantum-mechanical effect—namely photon antibunching. We describe here the recent prediction by Carmichael and Walls[3] and observation by Kimble, Dagenais and Mandel[4–6] and G. Leuchs, M. Rateike and H. Walther (personal communication) of this unique quantum-mechanical effect in photon correlation experiments of fluorescent light from a two-level atom. This marks a dramatic change from all previous photon correlation experiments since the photon antibunching observed cannot be explained on the basis of a classical description of the radiation field. We begin with a brief outline of events leading up to the present investigations.

The quantum theory of light

The quantum theory of light beginning with Planck[7] and Einstein[8] played a central part in the development of quantum theory during this century. As the quantum theory was developed a sophisticated theory for the interaction of photons and electrons namely quantum electrodynamics evolved. Amongst the predictions of quantum electrodynamics was that the emission of light from an atom would experience a small shift away from the resonance line of the atom. The experimental observation of this shift, known as the Lamb shift, came as a major triumph for the quantum theory of light[9]. However, for many experiments in optics especially in the field of physical optics the classical picture of light as propagating waves of electromagnetic radiation was adequate to describe the observations. The idea developed that it was not necessary to quantise the light field but only necessary to quantise the atoms and thus describe their interaction by a semiclassical theory. Modifications of this concept such as neoclassical radiation theory also developed. These theories can explain phenomena such as the photoelectric effect, spontaneous emission and even give estimates of the Lamb shift. (A discussion on the present status of such theories as an alternative to quantum electrodynamics is given in ref. 10.) An early attempt to find quantum effects in a physical optics experiment was made by Taylor[11] who performed Young's interference experiment at very low intensities such that on the average only one photon was incident on the screen at a time. Integrating over a long detection time Taylor obtained an interference pattern as predicted by classical wave theory with no evidence of any unique quantum effects. Taylor's experiment may also be explained on the basis of the quantum theory which interprets it as the interference of the quantum-mechanical probability amplitudes for the photon to go through one slit or the other[12,13]. Essentially the experiments of physical optics were in the regime of one photon or linear optics. We need to go outside the experiments of one photon optics in order to detect any uniquely quantum-mechanical effects.

Photon correlation experiments

The first experiment outside the domain of one photon optics was performed by Hanbury-Brown and Twiss in 1956. They performed an intensity correlation experiment, that is a measurement of $\langle I(t)I(t+\tau)\rangle$. Although the original experiment involved the analogue correlation of photocurrents, later experiments used photon counters and digital correlators[14–18]. In essence these experiments measure the joint photocount probability of detecting the arrival of a photon at time t and another photon at time $t+\tau$. The measurements made in this experiment may be described in terms of the second-order correlation function of the radiation field introduced by Glauber[2] in his formulation of optical coherence theory. This is defined as

$$g^{(2)}(\tau) = \frac{\langle E^{(-)}(t)E^{(-)}(t+\tau)E^{(+)}(t+\tau)E^{(+)}(t)\rangle}{(\langle E^{(-)}(t)E^{(+)}(t)\rangle)^2} \qquad (1)$$

where $E^{(+)}(t)$ and $E^{(-)}(t)$ are the positive and negative frequency components of the electromagnetic field respectively.

The result of a photon correlation measurement of $g^{(2)}(\tau)$ for a thermal light source using photomultipliers and digital correlators is shown in Fig. 1 curve *a*. We see that the joint counting rate for zero time delay is twice the coincidence rate for large time delays τ. That is, there is a tendency for the photons to arrive in pairs, or a photon-bunching effect. The decay time of the correlations is given by the inverse bandwidth of the light source.

If instead of a thermal light source the experiment is performed with a highly stabilised laser source one obtains a constant correlation function as shown in Fig. 1 curve *b*. This result holds even if the laser and thermal light source have the same bandwidth. Hence there is some fundamental difference between a laser and a thermal light source which may not be apparent in the first-order correlation function but which is manifest in the second-order correlation function. This effect may be understood by considering the photon statistics of different light fields.

Quantum theory of photon correlations

We shall attempt in this section to give a quantum theoretic interpretation of photon correlation experiments. For simplicity we shall concentrate on an interpretation of $g^{(2)}(0)$ which enables us to restrict our attention to a single mode field. For a single mode field we may write $g^{(2)}(0)$ in the form

$$g^{(2)}(0) = 1 + \frac{\sigma^2 - \bar{n}}{\bar{n}^2} \qquad (2)$$

where $\bar{n}$ and σ^2 are the mean and variance respectively of the photon number distribution. Thermal light has a power law photon number distribution with variance $\sigma^2 = \bar{n}^2 + \bar{n}$ which gives $g^{(2)}(0) = 2$. Coherent light on the other hand as produced by a highly stabilised laser has a poissonian photon number distribution[19–21] with $\sigma^2 = \bar{n}$ leading to $g^{(2)}(0) = 1$. This clearly yields the results shown in Fig. 1 for $g^{(2)}(0)$. To include the decay time of the correlation function one must consider many modes. For a field which has a photon number distribution narrower than a Poisson ($\sigma^2 < \bar{n}$) it is possible in principle to obtain a $g^{(2)}(0) < 1$. That is the photon coincidence rate for zero time delay is less than that for large time delays τ. This is the opposite effect to the photon bunching observed for thermal light and has been called photon antibunching. This represents a reduction in the photon number fluctuations below that of a poissonian distribution. The extreme case of photon antibunching would be a light beam where the photons arrive evenly spaced. For a single mode field this is equivalent to having a fixed photon number N which gives $g^{(2)}(0) = 1 - 1/N$.

Let us now consider a classical description of the electromagnetic field. We consider a field described by a fluctuating amplitude E. These fluctuations are taken into account by introducing a probability distribution $P(E)$ for the complex field amplitude. A calculation of $g^{(2)}(0)$ yields

$$g^{(2)}(0) - 1 = \frac{\int P(E)(|E|^2 - \langle|E|^2\rangle)^2 \, d^2E}{(\langle|E|^2\rangle)^2} \qquad (3)$$

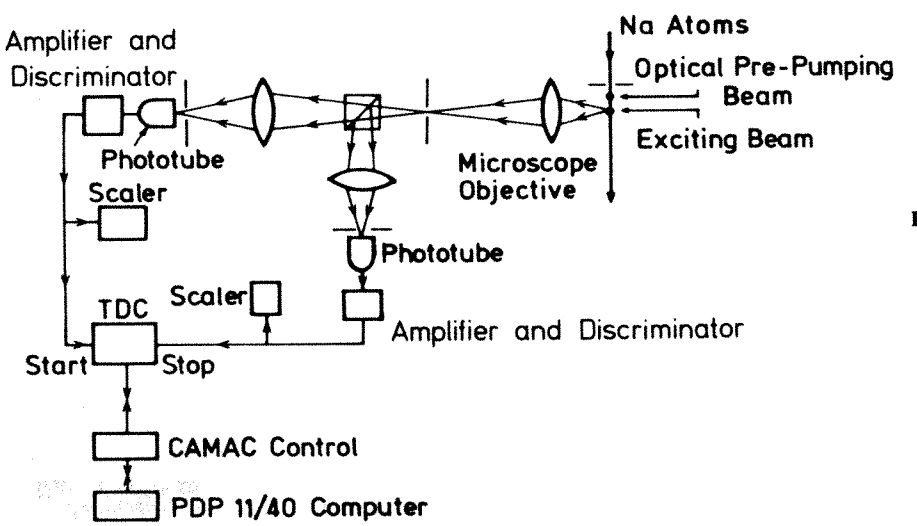

Fig. 3 Experimental arrangement used by Kimble *et al.*[4].

For a thermal field which has a gaussian distribution for $P(E)$ we recover $g^{(2)}(0)=2$ whereas for a coherent field with a stabilised amplitude $P(E)$ is a delta function and hence $g^{(2)}(0)=1$. Hence the Hanbury-Brown and Twiss effect for chaotic fields and indeed for the coherent laser field is adequately described by classical theory. However, since the right hand side of equation (3) is a positive semi-definite quantity, we see that classical theory requires $g^{(2)}(0)\geqslant 1$ and hence does not allow photon antibunching.

The formulation of the quantum theory closest in formal appearance to the classical theory involves the diagonal expansion of the density operator of the radiation field in terms of coherent states[2,22],

$$\rho=\int P(\mathscr{E})|\mathscr{E}\rangle\langle\mathscr{E}|\,\mathrm{d}^2\mathscr{E} \tag{4}$$

where the coherent states $|\mathscr{E}\rangle$ are eigenstates of the positive frequency part of the electromagnetic field

$$E^{(+)}|\mathscr{E}\rangle=\mathscr{E}|\mathscr{E}\rangle \tag{5}$$

with eigenvalue $\mathscr{E}$. The function $P(\mathscr{E})$ does not have the character of a probability distribution since for certain nonclassical states of the radiation field it may be negative or highly singular.

A calculation of $g^{(2)}(0)$ using the P representation yields

$$g^{(2)}(0)-1=\frac{\int P(\mathscr{E})(|\mathscr{E}|^2-\langle|\mathscr{E}|^2\rangle)^2 d^2\mathscr{E}}{\langle|\mathscr{E}|^2\rangle^2} \tag{6}$$

This appears similar in form to the classical expression of equation (3), however, since $P(\mathscr{E})$ may for certain fields which have no classical description take on negative values then $g^{(2)}(0)$ may be less than unity in quantum theory.

While this particular feature of quantum theory was recognised it remained to find a light field which exhibited the property of photon antibunching. It was suggested that certain processes of nonlinear optics for example sub-second harmonic generation[23–26] and two-photon absorption[27–33] would exhibit photon antibunching. To date there has been no experimental verification of these predictions. It was resonance fluorescence from a two-level atom that led to the first experimental observation of photon antibunching.

Resonance fluorescence from a two-level atom

The topic of resonance fluorescence from a two-level atom has been the subject of considerable theoretical and experimental investigation. For weak incident fields the light is coherently scattered, whereas for strong incident fields when the Rabi frequency Ω ($\Omega=2\kappa\mathscr{E}/h$ where $\mathscr{E}$ is the driving field amplitude and κ is the atomic dipole matrix element) exceeds the Einstein A coefficient γ of the atom the spectrum of the scattered light splits into three peaks with the two sidebands displaced from the central peak by the Rabi frequency. This spectrum first predicted by Mollow[34] was verified in detail by the experiments of Wu *et al.*[35] and Hartig *et al.*[36] following an earlier experiment of Schuda *et al.*[37]. These experiments used an atomic beam of sodium atoms which were optically pumped to prepare a pure two-level system. These atoms were then subjected to irradiation from a highly stabilised dye laser tuned to resonance with the atomic transition. This system was to prove of further interest to physicists.

Carmichael and Walls[3] predicted that the second-order correlation function of the light emitted by a single atom undergoing resonance fluorescence would exhibit the property of photon antibunching. This was confirmed in subsequent calculations by Cohen-Tannoudji[38] and Kimble and Mandel[39]. The results obtained by Carmichael and Walls for the second order correlation function $g^{(2)}(\tau)$ in the steady state are

$$g^{(2)}(\tau)=\left[1-\exp\left(\frac{-\gamma\tau}{2}\right)\right]^2 \quad \Omega\ll\gamma \tag{7}$$

$$g^{(2)}(\tau)=\left[1-\exp\left(\frac{-3\gamma}{4}\tau\right)\cos\Omega\tau\right] \quad \Omega\gg\gamma \tag{8}$$

in the limiting cases of very weak and very strong driving fields. The behaviour of $g^{(2)}(\tau)$ is plotted in Fig. 2. This system clearly displays the property of photon antibunching since in both limits $g^{(2)}(\tau)$ starts at zero. For low-intensity driving fields $g^{(2)}(\tau)$ rises monotonically to a background value of unity, whereas for high driving field intensities $g^{(2)}(\tau)$ rises above unity before reaching a steady state value of unity by damped oscillations.

This behaviour can be understood as follows. A measurement of $g^{(2)}(\tau)$ records the joint probability for the arrival of a photon at time $t=0$ and the arrival of a photon at time $t=\tau$. Consider now the driven two-level atom as our source of photons. The detection of a fluorescent photon prepares the atom in its ground state since it has just emitted this photon. The probability of seeing a second photon at $\tau=0$ is zero since the atom cannot re-radiate from the ground state. One must allow some time to elapse so that these may be a finite probability for the atom to be

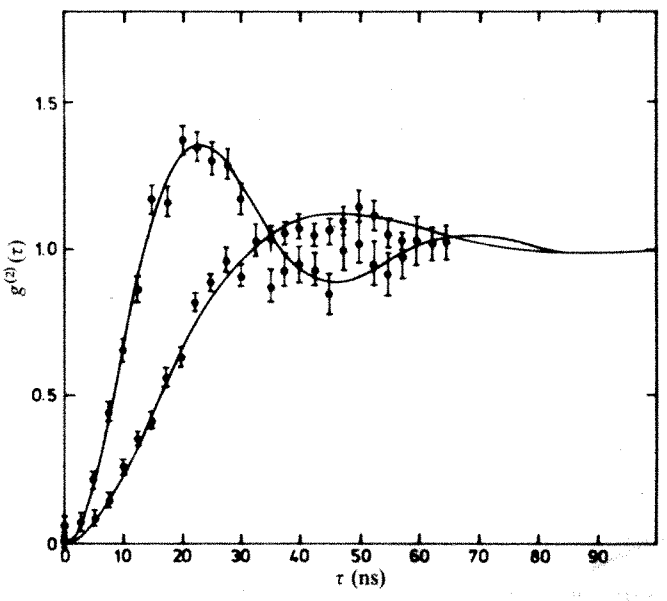

Fig. 4 Photon correlation measurements of fluorescent light from sodium. Experimental results obtained by Dagenais and Mandel compared with theory (solid line). ●, $\Omega/\gamma=2.2$; ○, $\Omega/\gamma=1.1$.

in the excited state and hence a finite probability for the emission of a second photon. In fact $g^{(2)}(\tau)$ is proportional to the probability that the atom will be in its excited state at time τ given that it was initially in the ground state.

Thus a single atom undergoing resonance fluorescence became a candidate for observing photon antibunching. However, the results (equations (7), (8)) hold only for resonance fluorescence from a single atom. If photons from many atoms contribute to the signal detected then one gets interference effects and the antibunching is diminished and for a large number of atoms lost entirely. In fact for a large number of independently contributing atoms one finds $g^{(2)}(\tau)=2$ in agreement with the central limit theorem[3].

It is clear therefore that an experiment of high sensitivity was necessary if measurements were to be made on the second order correlation function of light from a single atom. Such an experiment was performed by Kimble, Dagenais and Mandel[4]. A sketch of their experimental setup is shown in Fig. 3. In a similar configuration to the experiments which measured the spectrum they used an atomic beam of sodium atoms optically pumped to prepare a pure two-level system. The atomic beam was irradiated at right angles with a highly stabilised dye laser tuned on resonance with the $3P_{3/2}$, $F=3$, $M_F=2$ to $3^2S_{1/2}$, $F=2$, $M_F=2$ transition in sodium. The intensity of the atomic

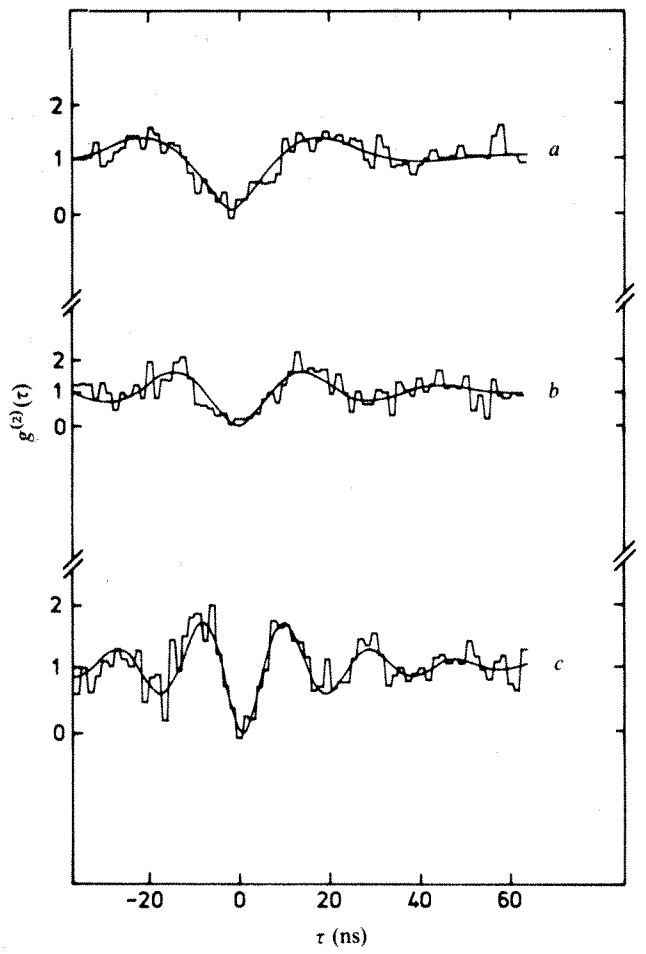

Fig. 5 Photon correlation measurements of fluorescent light from sodium. Experimental points adapted from the results of Leuchs *et al.* (personal communication) compared with theory. *a*, $\Omega/\gamma = 2.2$; *b*, $\Omega/\gamma = 4.3$; *c*, $\Omega/\gamma = 5.7$.

beam was reduced so that on the average no more than one atom is present in the observation region at a time. The fluorescent light from a small observation volume is observed in a direction orthogonal to both the atomic and laser beams.

The fluorescent light in this direction is divided into two equal parts by a beam splitter and the arrival of photons in each beam is detected by two photomultipliers. The pulses from the two detectors are fed to the start and stop inputs of a time to digital converter (TDC) where the time intervals τ between start and stop pulses are digitised in units of 0.5 ns and stored. The number of events $n(\tau)$ stored at address τ is therefore a measure of the joint photoelectric detection probability density which equals $\eta^2 g^{(2)}(\tau)$ where η is the detector efficiency. The initial results obtained by Kimble *et al.*[4] showed the initial positive slope of $g^{(2)}(\tau)$ characteristic of photon antibunching but starting with $g^{(2)}(0) = 1$ rather than zero.

The reason for this disagreement with the theory was pointed out by Jakeman *et al.*[40] who attributed it to number fluctuations in the atomic beam. Though the atomic beam density is such that on the average only one atom is in the observation volume during a correlation time, there are poissonian fluctuations about this mean value so that at times there could be two or more atoms in the observation volume. Thus in the atomic beam experiment one observes the photon antibunching superimposed on the poissonian number fluctuations of the atoms. A calculation including the atomic number fluctuations was carried out by Carmichael *et al.*[41] Similar calculations were made by Kimble *et al.*[5] who obtained very good agreement with experimental results. Some recent experimental results of Dagenais and Mandel[6] are shown in Fig. 4, where when the effects of atomic number fluctuations are taken into account excellent agreement is obtained with the theory. A photon correlation experiment on resonance fluorescence from a beam of sodium atoms has been recently performed by Leuchs *et al.* (personal communication). The results of this experiment are shown in Fig. 5, where with compensation for the atomic number fluctuations excellent agreement is found with the theory. These experiments show clear evidence for the existence of photon antibunching and thus verify the predictions of the quantum theory of light.

Discussion

It could still be argued that one has not observed light with the antibunching property but only inferred from the experimental observation that the fluorescent light from a single atom must possess the antibunching property. This is due to the finite correlation at $\tau = 0$ arising from the number fluctuations of the atoms. It would be useful, therefore, to consider ways of improving experimental methods. Recently advances have been made towards isolating a single atom in an ion trap[42]. This suggests the possibility of performing resonance fluorescence on a single stationary atom which should radiate light with the antibunching character. In addition there are the suggested systems in nonlinear optics for example, sub-second harmonic generation[23–26] and two-photon absorption[27–33] where photon antibunching has been predicted. These experiments involve the nonlinear coupling of electromagnetic waves through a medium which may be in the solid state thereby eliminating problems due to atomic number fluctuations.

Although minor refinements may be possible the experiments performed by Kimble *et al.*[4–6] and Leuchs *et al.* (personal communication) represent a fundamental contribution to our understanding of the nature of light. For the first time photon correlation experiments have detected an effect which is a direct manifestation of the quantum nature of light.

Population biology of infectious diseases: Part II

Robert M. May
Biology Department, Princeton University, Princeton, New Jersey 08544

Roy M. Anderson
Zoology Department and Centre for Environmental Technology, Imperial College, London University, London SW7, UK

In the first part of this two-part article (Nature **280**, *361–367*), *mathematical models of directly transmitted microparasitic infections were developed, taking explicit account of the dynamics of the host population. The discussion is now extended to both microparasites (viruses, bacteria and protozoa) and macroparasites (helminths and arthropods), transmitted either directly or indirectly via one or more intermediate hosts. Consideration is given to the relation between the ecology and evolution of the transmission processes and the overall dynamics, and to the mechanisms that can produce cyclic patterns, or multiple stable states, in the levels of infection in the host population.*

IN the first part of this article[1] we considered the dynamics of microparasitic infections with direct transmission between hosts. We now extend the discussion to other kinds of parasites and transmission processes, and examine the general relations between population behaviour and parasite life cycle structure. The conclusions are broadly similar to those in the first part[1], but there are interesting similarities and differences both in the mathematical structure and in the biological conclusions.

We then give a brief discussion of general evolutionary trends, and end with a survey of the main mechanisms that can produce cyclic patterns, or multiple stable states, in the levels of infection in the host population.

Life cycle structure and disease dynamics

Macroparasites with direct life cycles tend to produce persistent infections, with the host harbouring populations of parasites for long periods, due to continual reinfections. Among many examples are the hookworm species of man, *Ancylostoma duodenale* and *Necator americanus* (see Table 1); in endemic areas the prevalence of these infections may approach[2] 100%. For such systems, the pathogenicity to the host, the rate of production of transmission stages of the parasite and any resistance of the host to further infection all typically depend on the number of parasites present in a given host. A crude division of the host population into susceptible, infected and immune classes is therefore not helpful, and a detailed description of the dynamics needs to deal with the full probability distribution of parasites within the host population[3–6] (that is, with the number of hosts harbouring i parasites $N(i)$, where $i = 0, 1, 2, \ldots$). Figure 1, which is to be compared with Fig. 3 of the first part of this article[1], depicts the essential structure of such models.

It is often useful to simplify these models by making a phenomenological assumption about the statistical distribution of parasites among hosts[3,7–10] (or even, occasionally, by making assumptions that permit this distribution to be deduced theoretically[11,12]). A usual phenomenological assumption is that the parasite distribution is a negative binomial[3,7–10,13,14], with the parameter k providing an inverse measure of the degree of parasite 'clumping' or overdispersion within the host population; the limit $k \to \infty$ corresponds to the parasites being distributed in an independently random or Poisson form, while very small k corresponds to very high clumping. It is then possible to use such statistical moments of the $N(i)$ distribution as the total host population ($N = \sum_i N(i)$), the number of uninfected hosts ($X = N(0)$), the total parasite population ($P = \sum_i iN(i)$), and the mean parasite burden per host ($m = P/N$). In this way, models of the kind depicted in Fig. 1 can be brought into correspondence with the coarser models of the kind discussed in Part I (see Fig. 3 of Part I)[1].

The most detailed study of this type[3,4] draws on a synoptic collection of data for direct life cycle parasites (mainly helminths), and describes the dynamics in terms of three differential equations, for the number of hosts N, parasites P, and free-living infective stages w:

$$dN/dt = (a-b)N - \alpha P \quad (1)$$

$$dP/dt = \beta wN - (\mu + b + \alpha)P - \alpha(k+1)P^2/(kN) \quad (2)$$

$$dw/dt = \lambda P - cw - \beta wN \quad (3)$$

Here the birth and death rates a and b are as defined in the first part[1] of this article, as is the transmission parameter β (hosts acquire individual adult parasites at a rate proportional to the number of contacts between hosts and parasite infective stages, βwN). The parasite-induced host death rate (or, equivalently, depression of the birth rate) is taken to be linearly proportional to the parasite burden in a given host, at a rate α per parasite. The parasites are distributed as a negative binomial with parameter k; μ is the natural mortality rate of adult parasites; λ is the rate of production of infective stages by an adult parasite; and c is the death rate of these infective stages. The biological underpinning of these equations, and their dynamical behaviour, have been expounded in detail elsewhere[3,4].

A rough understanding of the relation between this system of equations for typical macroparasites with direct transmission, and the earlier set of equations (8)–(10) of Part I for directly transmitted microparasites, can be obtained as follows. First, note that the lifespan of the free-living infective stages is usually much shorter than that of the host and the adult parasite (compare Table 1). Thus the set of differential equations can be decoupled, by assuming the 'short lived' infective stages are adjusted essentially instantaneously to their equilibrium level ($dw/dt = 0$) for any given value of N and P. This gives

$$dN/dt = rN - \alpha P \quad (4)$$

$$dP/dt = \frac{\lambda NP}{H_0 + N} - (\mu + b + \alpha)P - \frac{\alpha(k+1)P^2}{kN} \quad (5)$$

(where $r = a - b$ and $H_0 = c/\beta$). Second, a phase-plane analysis now lays bare the properties of this pair of equations.

Three patterns of dynamical behaviour are possible[3,4]. (1) If

$$\lambda - (\mu + b + \alpha) > r(k+1)/k \quad (6)$$

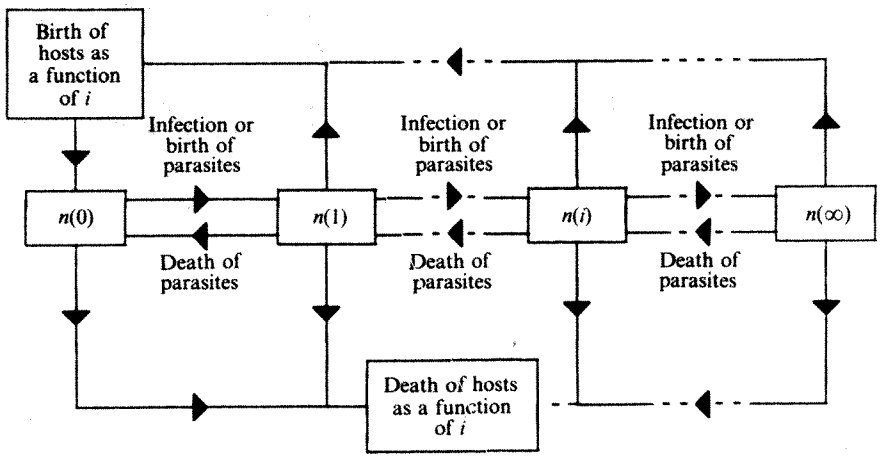

Fig. 1 Diagrammatic flow chart for a directly transmitted infection, based on a model with compartments for the number of hosts, $N(i)$, harbouring i parasites ($i=0, 1, 2, \ldots$). The model has a structure similar to, but obviously more complex than, that of Fig. of 3 Part I[1].

the parasite regulates the host population to a stable equilibrium value. The average parasite burden per host settles to

$$m = r/\alpha \tag{7}$$

(2) If Equation (6) is not satisfied, but

$$\lambda - (\mu + b + \alpha) > 0 \tag{8}$$

the host population continues to grow exponentially, but at a rate

$$\rho = r - [\lambda - (\mu + b + \alpha)][k/(k+1)] \tag{9}$$

This is less than the disease-free rate, r. In this case, the mean parasite burden in the exponentially growing host population settles to the value

$$m \to (r - \rho)/\alpha \tag{10}$$

In either event, if the host population is initially below the value

$$N_T = \frac{H_0(\mu + b + \alpha)}{\lambda - (\mu + b + \alpha)} \tag{11}$$

the parasite cannot become established ($dP/dt < 0$). However, as long as equation (8) is satisfied, the host population will grow exponentially (at the rate r) until this threshold value N_T is exceeded, whereupon the infection will become established, either regulating the host population or at least slowing its growth rate. Furthermore, in view of the large values for the reproductive output λ of most helminth parasites, N_T will typically be relatively small. This expectation of commonly finding direct life cycle helminth infections persisting in low density host populations is borne out by the evidence[15,16].

(3) Finally, if λ is so small that equation (8) is not satisfied, the infection can never become established (N_T is negative!).

The similarities between cases (1) and (2) here, and the results displayed in Fig. 4 of Part I, are striking. In particular, for measures of the prevalence of infection, notice the exact formal equivalence between equation (15) of Part I and equation (7), and between equation (17) of Part I and equation (10). A dissimilarity is that whereas the ability of a microparasitic infection to regulate its host population essentially depends on its pathogenicity α exceeding the host population growth rate r (weighted by rates of recovery, loss of immunity and so on: see Table 1 of Part I), for a macroparasite it is its net reproductive ability, $\lambda - (\mu + b + \alpha)$, that plays a central role (λ is the 'birth rate', while μ, b and α are the natural parasite, natural host and parasite-induced host death rates). The macroparasitic infection can never persist if this effective net reproductive rate is not positive (equation (8)). The parasite will regulate the host population, or merely slow its growth, depending on whether this effective net reproductive rate $\lambda - (\mu + b + \alpha)$ is, or is not, greater than the host reproductive rate r, weighted by a factor $(k+1)/k$ to allow for the clumped distribution of parasites. Thus equation (6) is for these directly transmitted macroparasites the analogue of the microparasite equation (13) in Part I[1].

Table 1 Expected lifespans of the host and parasitic stages involved in the life cycle of *Schistosoma mansoni* and *Ancylostoma duodenale*

	Population	Lifespan (yr)
S. mansoni (refs 24, 29, 82)	Man (primary host)	50.00
	Adult parasite	5.00
	Infected snails (intermediate host)	0.10
	Cercariae	0.003
	Miracidia	0.0009
A. duodenale (ref. 2)	Man	50.0
	Adult parasite	1.0
	Free-living infective stage	0.1

Indirect life cycles constitute another qualitatively different kind of complication, arising when the life cycle of the parasite involves one or more intermediate hosts. This happens for both microparasites (for example, the arthropod-borne viruses or arboviruses such as yellow fever or Rocky Mountain spotted fever; the protozoan malaria species) and macroparasites (for example, schistosomes, the filarial worms causing onchocerciasis, and other roundworms and flatworms that involve dipteran, molluscan and other intermediate hosts). Malaria and schistosomiasis in human populations are the two parasites whose transmission cycles have been most fully studied and each enjoys its own independent and growing literature, both empirical and theoretical (see Table 2). Their basic dynamical character is, however, in many respects common to all parasites with indirect life cycles.

If we adopt the approach of equations (8)–(10) and Fig. 3 discussed in part I, namely dividing the host population into susceptible, infected and immune categories, we will in the simplest case have a system of six differential equations: three for the primary host (alternatively referred to as the definitive host, or final host) classes X, Y, Z; three for the intermediate host populations X', Y', Z'. All existing models, however, assume the total populations of both primary host ($N = X + Y + Z$) and the intermediate host ($N' = X' + Y' + Z'$) are constant, unaffected by the dynamics of the disease. This reduces the system to four equations. If, furthermore, immunity is either ignored or handled by specific assumptions about 'superinfection', the Z and Z' classes are effectively removed to give two coupled differential equations for the number of primary hosts Y, and of intermediate vectors Y', that are infected. This, in essence, is the source of the classic Ross-Macdonald[17,18] malaria equations, the Nasell–Hirsch[19] schistosomiasis model, and the Dietz[20] arbovirus equations.

These equations have been subjected to various kinds of more refined treatment, including age structure[20–24], immunity and 'superinfection'[17,21,23–26] and the use of several immunological categories of hosts[26] (intermediate between Fig. 3 of Part I and Fig. 1 of Part II). However, essentially all the existing work on

indirectly transmitted parasites retains the assumption that the populations of host and intermediate vector are constant, not dynamically involved with the infection. Analysis of such models reveals threshold relations[17,20,21,27,28] between N and N', analogous to but more complicated than the N_T of the direct life cycle models. If N and N' lie below the threshold combination, the disease cannot be maintained.

For many human, and other animal, infections by parasites with indirect life cycles, what is needed is a theory in which the populations of primary and intermediate hosts are affected, and possibly even determined, by the presence of the infection. While it may often be reasonable to treat a human primary host population as roughly constant, we believe that cases where intermediate host populations are unaffected by the prevalence levels of the infection will be the exception rather than the rule[29]. There is no formal problem in extending our dynamic models of either the 'microparasite' kind of equations (8)–(10), (Part I) or the 'macroparasite' kind of equations (1)–(3) (Part II), to encompass the added complication of one or more intermediate vector populations. Space forbids a full exposition of the emergent properties, but the main trends are indicated in the following section.

Time scales and transmission terms

A full model for an indirectly transmitted parasite might include not only dynamical descriptions of the prevalence of infection in primary and intermediate host populations, but also additional differential equations (analogous to equation (3)) for the free-living transmission stages that carry the parasite from primary to intermediate host, and back again. For example, for schistosomiasis we could add a differential equation describing the miracidial stage (man to snail), and another for the cercarial stage (snail to man), to the usual equations for infection levels in the human and snail populations[30]. The reason this is not commonly done can be seen from Table 1; the dynamics of the free-living stages takes place on a time scale so much shorter than the other time scales in the system that miracidial and cercarial populations can be assumed to have the equilibrium values appropriate to the prevailing conditions among human and snail populations. In just this way, we collapsed the three-equation system (1)–(3) to the two equations (4), (5).

This technique of using biological insights about the time scales of various infection processes can be used to make further rough but useful approximations. For example, the time scales for processes (such as mortality rates) within the intermediate host population are typically significantly shorter than those in the primary host. Again, Table 1 testifies to this. Accordingly, we can assume that the numbers of susceptible, infected and immune intermediate hosts are adjusted to have the equilibrium values ($dX'/dt = 0$, and so on) appropriate to the current levels of infection in the primary hosts. In this way, parasitic infections with indirect life cycles can be approximately brought to a form similar to that of equations (8)–(10) in Part I for direct life cycles[1].

As a concrete example, consider a grossly oversimplified model for malaria, in which 'superinfection'[17,25,26], and mosquito latency[17,21] (and immunity[20,26]), are ignored. Assume also the total mosquito population is constant; $N' = X' + Y' =$ constant. The populations of infected humans Y, and mosquitos Y', then obey

$$dY/dt = \beta' Y' X - (b + \alpha + v)Y \quad (12)$$

$$dY'/dt = \beta Y(N' - Y') - (b' + \alpha' + v')Y' \quad (13)$$

Here β, b, α and v (plain for humans, primed for mosquitos) have their previous meanings; conventionally, most infected humans are assumed to recover ($v \gg \alpha, b$), and most infected mosquitos to die at a rate largely unaffected by the infection ($b' \gg \alpha', v'$). The assumption that mosquito processes happen on a relatively fast time scale enables Y' in equation (12) to be determined by setting $dY'/dt = 0$ in equation (13), leading to

$$dY/dt = Y[(\beta\beta' N' X)/(b' + \alpha' + v' + \beta Y) - (b + \alpha + v)] \quad (14)$$

This is exactly of the form for a directly transmitted infection (equation 9 of Part I), except that the simple transmission coefficient β has been replaced by the more complicated factor $\beta\beta' N'/(b' + \alpha' + v' + \beta Y)$. Similarly, the Nasell–Hirsch two equation model[19] for prevalence of schistosomiasis among humans and snails can be collapsed to Macdonald's[27,28] single equation for prevalence in the human population.

Conversely, for humans the total population is often growing on a time scale that is long compared to the relevant time scales of even persistent infections. This is why the total population can be treated as a constant in most epidemiological models. The approximation, whereby the dynamics of the prevalence (Y/N) and of the total population (N) are decoupled, can often be useful in discussing the transmission cycle of the infection, even though the long-term growth or regulation of the host population is affected by the presence of the infection.

Table 2 uses these ideas to attempt to give a schematic account of the relations among some of the many models, of differing degrees of complexity, that are to be found in the literature.

Saturation of transmission terms. The transmission terms obtained in equation (14) by 'collapsing out' the mosquito dynamics of equation (13), and in equation (5) by collapsing equation (3) for the free-living infective stages of the parasite, manifest a feature that is common to all such approximate representations of complex transmission processes[3,4,14,31,32]. Essentially, the simple term βXY for direct transmission

Table 2 Schematic representation of relationships between various kinds of models for parasitic infections, based on relative time scales of population processes

	Host population(s) constant	Host population(s) a dynamic variable
In considering the dynamics of infection, only one species is involved (for example, the host species).	**Direct life cycles** Classical epidemiological models (refs 21, 56, 65, 67, 83–84, 87). Models for the dynamics of a parasite population within a host population of fixed size (refs 5, 88, 89). **Indirect life cycles**. Models for schistosomiasis (refs 28, 34, 90) and for malaria (refs 17, 18, 21), considering only the dynamics within the human host.	**Direct life cycles**. Models similar to those for classical epidemiology, but with total host population a dynamic variable, determined by birth and death processes (refs 35, 91 and this review). **Direct and indirect life cycles**. Dynamics of models in the compartment below but with all populations but the primary host 'collapsed out' (this review).
In considering the dynamics of infections, two or more species are involved (e.g., primary *and* intermediate host, or host *and* parasite population).	**Direct life cycles**. Models similar to the classical epidemiological equations, but including the dynamics of free-living infective stages (ref. 35). **Indirect life cycles.** Models for schistosomiasis (refs 19, 34, 92), malaria (refs 17, 21, 93) and arbovirus infections (ref. 20) in which both human hosts and intermediate vectors are considered. Models of schistosomiasis where humans, snails, miracidiae and cercariae are all considered (ref. 30).	**Direct life cycles.** Models similar to classical epidemiology, but with host population and free living infective stages both included as dynamic variables (ref. 35). Models for dynamics of host parasite systems (refs 3, 4, 7, 8, 14, 35), sometimes with dynamic aspects of free-living infective stages also included (refs 3, 4). **Indirect life cycles.** Any of the models in the compartment to the left, but with the total host populations treated as dynamic variables (this review).

between susceptible and infected people or βNw for direct transmission between hosts and free-living infective stages are replaced by expressions of the general form $AXY/(1+\nu Y)$ or $ANP/(1+\nu N)$, respectively. In the limit when, for example, νY is small, the expression has the familiar form, proportional to X and Y. But it can be that νY becomes significant compared to unity, whereupon the transmission term saturates to a value (AX/ν) proportional only to X. Such saturation effects can be important in diminishing the ability of the parasite to regulate its host population[3,14].

Ecology of the transmission process. Further complications can arise from the ecological nature of the individual links in the transmission process.

For infections that are communicated directly, the assumption that the net rate is proportional to the number of susceptibles and to the number of infectives is clearly reasonable for many diseases, and strikingly successful in explaining the mouse pox and mouse pasteurellosis data[1]. But for sexually transmitted diseases, for example, this is only plausible in a population that is astonishingly promiscuous and sexually active. In a society whose members typically have only a small number, η, of sexual partners (independent of the absolute population size), the rate at which an infected person propagates the infection is proportional not to the total number of susceptibles, but to η times the probability that a given person is a susceptible; that is, βXY is to be replaced[21] by $\beta\eta XY/N$. Under these very simple assumptions, the condition for maintenance of such diseases is $\beta\eta > (b+\alpha+\upsilon)$, independent of the population size. In reality, a more careful treatment of the distribution of degrees of sexual activity within the population is needed[33], but the fact remains that infections of this sort are relatively easy to maintain in low density populations.

More broadly, biological insights into the relative time scales associated with the various phases of indirect life cycles enable us to discuss the prevalance of infection in the primary host population by retaining equations (8) and (10) for X and Z, in Part I of this article, but replacing equation (9) with the more general expression

$$dY/dt = Y[h-(a+b+\upsilon)] \tag{15}$$

The transmission term is here denoted by h (Ross' 'happenings'[18]), and the threshold condition for the disease to increase upon introduction at low levels is clearly that $h > (\alpha+b+\upsilon)$ in the limit $Y \to 0$. For the simple circumstances of the indirect life cycle that led to equation (14) above, this requirement comes down to the threshold criterion[20,21]

$$NN' > \frac{(\alpha+b+\upsilon)(\alpha'+b'+\upsilon')}{\beta\beta'} \tag{16}$$

Note that a large population N' of intermediate vectors can enable the disease to persist, even when the primary host population N is small.

However, for malaria and many other infections borne by biting arthropods, the intermediate vector tends to make a fixed number of bites per week, independent of the number of primary hosts available to feed on. Thus the transmission rate from infected arthropods to people (and from infected people back to susceptible arthropods) is proportional to the biting rate ω times the probability that a given human is susceptible (or infected), and not simply proportional to the number of susceptible (or infected) people. That is, in equations (12) and (13), β and β' are to be replaced by ω/N. The threshold condition (16) is accordingly modified to[17,18,20]

$$\frac{N'}{N} > \frac{(\alpha+b+\upsilon)(\alpha'+b'+\upsilon')}{\omega^2} \tag{17}$$

Note that latency effects have been neglected here, although they can be important in infections with indirect life cycles, and they certainly modify threshold conditions significantly for malaria[17] and schistosomiasis[29]. Infections with intermediate vectors of this character are relatively easy to maintain at low population densities of the primary host, provided only that the ratio of intermediate to primary hosts is sufficiently high. Indeed, equation (17) suggests the infection is actually easier to maintain at low host population levels; the mosquito or other intermediate host population N' is, however, typically dependent on the primary host for blood meals or the like, so that things are not as simple as they might seem. (A more general discussion, from which the threshold relations (16) and (17) emerge as limiting cases, has been given by Dietz[20]).

Yet another form of complication enters with parasites that have sexual stages, yet can have low densities, in a host. Schistosomiasis is one such example[10,19,27,28,34]. At high levels of prevalence of the infection in the human population, people tend to have worm burdens such that most adult female schistosomes are mated, and the circumstances leading to equation (16) are well approximated. But at low levels of prevalence, it can be that the average female is not mated, which tends to require that the transmission link from snail to man be counted twice in considering the overall cycle, thus giving complicated threshold conditions (very roughly of the form $N[N']^2 >$ constant[19,34]).

Finally, note that (apart from the laboratory experiments on mice[1]) in all our models the host population either is regulated to some stable value by the disease, or else it grows exponentially. In practice, other constraints, set by resources, predators or the like, will eventually limit population growth. Such biological realities can be included in all our models, by introducing a logistic constraint (at a 'carrying capacity' K) in the growth of the disease-free population[35]. The resulting situation, for both direct and indirect parasite life cycles, is similar to that illustrated in Figs 1*e*, *f* and 2*b* in Part I, with the host population depressed below its disease-free level K, provided the parasite-induced host mortality α is not too large[1]. Too small an α leads to relatively little depression of the host population; too large an α renders the disease unable to persist, and the host population remains at K; maximum parasite-induced depression of the host population is attained for intermediate levels of pathogenicity[1,36]. This broad statement glosses over many intricacies that can arise (R.M.M. and R.M.A., in preparation), particularly with indirect life cycles when the intermediate vector has a constant biting rate (producing threshold conditions such as equation (17) in simpler models), but the gist is true.

Population parameters and evolutionary trends

Any discussion of the relations among the population parameters that characterize an infectious disease must ultimately take account of the evolutionary pressures on both hosts and parasites. Population dynamics is always confounded by population genetics.

For example, even if we assume no genetic change in the parasite, its action on the host will select for individuals with reduced susceptibility to the disease. For this reason alone, the pathogenicity of the parasite will tend to decrease through evolutionary time. Conspicuous examples are provided by the presence of the sickling gene (and other blood-group phenomena) in regions where malaria is endemic[37], and by the history of myxomatosis in rabbit populations in Australia[38]. An interesting theoretical discussion has been given by Gillespie[39].

Selective forces also act strongly on the parasites[40,41]. As we have seen, the persistence of a disease is facilitated by low pathogenicity and by long duration of infection[1]. Countervailing forces can, however, act to increase the virulence of an infectious disease; increased pathogenicity may often be associated with enhanced rates of production (within the host) of the parasite's transmission stages[38,42,43].

The regulatory potential of an infectious disease will, therefore, typically change as time goes by. A parasite may stably regulate its host population during their early association. But,

as selective pressures reduce the average susceptibility of the hosts, such regulatory effects will tend to wane. Eventually, the host population may escape being controlled by the parasitic infection.

Because the generation times of most hosts are several orders of magnitude longer than those of their parasites, it is tempting to conclude that selection acts more rapidly on the parasites. However, the way parasitic infections act within host populations makes it likely that the parasites force the pace of host evolution to keep in step with, or even ahead of, their own evolution.

Among the recondite variety of strategies that parasites have evolved for persistence and transmission, some general trends can be discovered. For example, many parasitic species traverse links in community food webs by virtue of predator–prey associations between primary and intermediate hosts. Such associations, which include biting arthropods feeding on vertebrates, have played an important part in the evolution of complex life cycles. The high transmission efficiency β of these links suggest the threshold host populations for maintenance of such parasites will be low (see equations (16) and (17)). Consequently, we expect indirect life cycles to predominate among parasitic infections of hosts that exist at low density.

In contrast, directly transmitted microparasites that require high host densities in order to persist should be more commonly associated with animals that exhibit herd or shoaling behaviour, or breed in large colonies. Empirical evidence in support of these ideas comes from the abundance of directly transmitted viral and bacterial infections within modern human societies[42,44], large herds of ungulates[45], breeding colonies of sea birds[46,47], and the social insects[48,49]. Those diseases with direct life cycles that do persist within low density host populations should possess distinctive characteristics, such as long-lived infective stages[50,51], failure to induce lasting immunity[33,52–53], or ability to persist within the host for very long times[54].

Another trend to be noted is that highly pathogenic species usually exist, if at all, at low levels of prevalence (see equations (15) and (17) in Part I and equations (7) and (10) in Part II). An example is the digenean parasite *Haematolaechus colaradensis* whose primary host is frogs, but which has a transmission pathway involving first snails, and then dragonflies, as intermediate vectors on the way to the next frog. The prevalence among frogs is high, 60–70%, and the parasite is long-lived and has very low pathogenicity; in dragonflies the fluke induces moderate mortality, and has 30–40% prevalence; while in snails it is highly pathogenic but appears to have only about 5–10% prevalence[55]. These broad patterns, which are often found in helminths with life cycles involving two or three host species, are summarized schematically in Table 3.

Cyclic patterns of disease prevalence

Annual or other cycles in the prevalence of infection are often observed, and can arise in at least three distinct ways.

First, for many short-lived viral and bacterial infections in human populations, there is a propensity for the steady, endemic level of prevalence of infection to be attained by damped oscillations. Particularly if this equilibrium prevalence is low, it is possible for stochastic fluctuations in the number of people infected at the minimum of the cycle to, in effect, keep the cycle 'pumped' and prevent it from damping to equilibrium. This interplay between demographic stochasticity and an inherent propensity to weakly damped oscillations is essentially the mechanism proposed in the classic work of Bartlett[21,56–59] to account for cyclic patterns in the prevalence of measles and other viral infections in large cities. Gurney and Nisbet[60] have proposed a similar mechanism as an explanation for predator–prey cycles.

Second, time dependence in any of the population parameters may, in principle, produce cyclic variations in infection. In particular, seasonal variation in the transmission coefficient is important in setting temporal patterns for many parasitic infections, and may often be central for human viral infections[44,61–65]. The mechanisms underlying the seasonality in the transmission rates are poorly understood, but for human viruses the main causes are probably climatic (temperature and humidity) effects influencing survival and dispersal of transmission stages, and seasonal changes in social behaviour[66,67] (children returning to school after the long summer vacation). The seasonal cycles characteristic of the prevalence of measles, chicken pox, poliomyelitis and mumps in large cities could arise in this way[21,44,65].

Annual periodicity in transmission rates can, moreover, produce complicated nonseasonal cycles in the prevalence of infection. Yorke and co-workers[44,63,65], and Dietz[64], have cogently argued that such a mechanism is responsible for the regular biennial cycle, alternating between years of high and low incidence, for measles in New York City between 1948 and 1964; in the same city, mumps and chicken pox showed clear annual cycles. The explanation of Yorke *et al.* is to the contrary of the conventional explanation of these non-seasonal cycles in terms of demographic stochasticity, as described above. Their model is essentially the set of deterministic equations (1)–(3) in Part I, with an assumed constant number of new susceptibles appearing each year, life-long immunity, and with the system enriched by the inclusion of a brief incubation period during which infected hosts are not infective. The basic feature is that the transmission coefficient $\beta(t)$ varies seasonally with a 1 yr period. Within a narrow window of parameter values, the number of infected people can show biennial peaks (Fig. 2*a*) similar to those for measles in New York City. This window separates highly transmissable diseases which produce an epidemic with eventual fade-out, from the diseases with low transmission efficiency which give rise to endemic seasonal patterns of infection (Fig. 2*b*), as usually shown by mumps and chicken pox.

Third, various kinds of nonlinearities in the transmission terms may produce stable limit cycles, whose periods depend on the population parameters and will rarely be seasonal. People familiar with the ease whereby stable limit cycles arise in predator–prey models may be surprised to learn the structure of most host–parasite models is such that stable cycles do not easily occur. However, they can be produced without excessive contrivance. One simple example is to take the basic equations (8)–(10) of part I, and introduce the possibility of saturation in the transmission by replacing βXY by $\lambda XY/(H_0+X)$. Such a modification can arise naturally[4,35], in the manner of the analogous expression in equations (5) and (14), if the term is thought of as deriving from the 'collapsed' dynamics of a free-living infective stage. This system can now exhibit stable limit cycles for a specific range of parameter values (corresponding to λ neither too small nor too large). One such stable cycle is illustrated in Fig. 2*c*. In general, however, little is yet agreed about the kinds of biological processes that can generate nonseasonal patterns of disease prevalence.

Table 3 Some population characteristics of diseases caused by indirectly transmitted helminths

Host	Pathogenicity of parasite	Prevalence of infection within host population	Expected life span of host (inversely related to time scaled dynamics)
Final	Low	High	Long
Second intermediate	Medium	Medium	Medium
First intermediate	High	Low	Short

Multiple stable states of disease prevalence

A growing number of empirical and theoretical studies suggest that many natural assemblies of plants and animals can have a multiplicity of alternative stable states[68]. Once two or more stable statesare possible, the actual state the system settles into

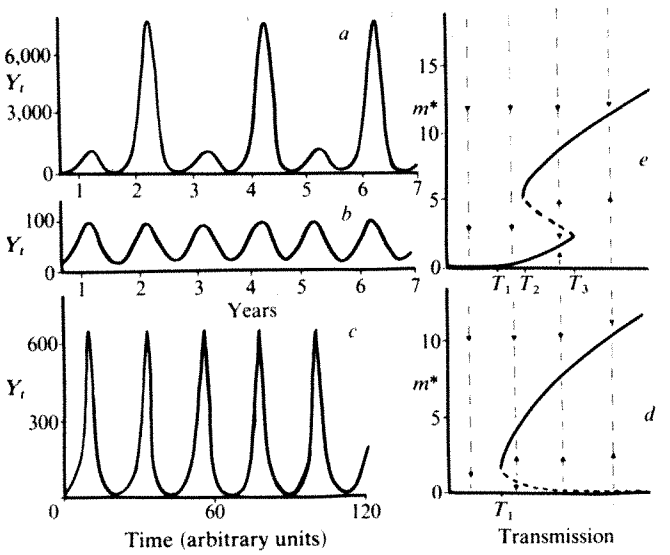

Fig. 2 *a*, Simulations of recurrent outbreaks of measles in New York City, showing biennial peaks superimposed on an underlying seasonal cycle (from London and Yorke[44]). *b*, Simulations[44,63] of recurrent outbreaks of mumps in New York City, with simple seasonal peaks, annually. *c*, Simple limit cycle behaviour generated by the model described in the text. *d*, The transmission threshold, alternative stable states, and 'breakpoint' phenomena that arise in simple models for the transmission dynamics of schistosomiasis[10,19,27,28,34]; the features are as discussed in the text. *e*, Transmission threshold and alternative stable states arising in a model for directly transmitted helminth infections, where it is assumed that the pathogenicity of the disease is related to the nutritional state of the host[35]. The graph shows the mean equilibrium burden of parasites per host, m^*, as a function of a parameter, T, representing transmission efficiency. The infection cannot persist below a threshold value T_1; between T_1 and T_2 there is a unique low level of disease endemicity; between T_2 and T_3 two stable levels of prevalence may occur, one high and the other low, separated by a breakpoint (the dashed line); above T_3 there is again a unique equilibrium level, corresponding to high average parasite burdens per host. The arrows indicate the stable state to which the system will sw from a given initial value.

depends on the initial conditions. The system will tend to recover its original configuration if subject to small disturbance, but sufficiently severe perturbations are liable to precipitate it into an alternative state in a different region of the dynamical landscape.

The nonlinearities in population models for parasitic infections can generate such multiple states by three principal mechanisms: worm pairing for sexual reproduction in the primary host; nonlinearities associated with the transmission from primary to intermediate host, or vice versa (mosquitos biting man for malaria, or predatory primary hosts consuming infected intermediate-host prey); parasite pathogenicity dependent on the nutritional state of the host.

The first and most fully studied of these categories arises for many helminth infections with indirect life cycles, such as schistosomes[10,19,27,28,34]. It serves to exemplify the phenomenon. As portrayed in Fig. 2*e*, the equilibrium value of the mean parasite burden per human host (m) will be zero if the rate of transmission (T) from snail to man is below the threshold value T_1. Above this threshold, two alternative stable states occur, one of endemic infection ($m > 0$), the other of parasite absence ($m = 0$). The basic reason is that at low levels of m the female worms are unlikely to be mated, so that the disease cannot be maintained, even though the transmission parameters are such as to permit its endemicity if introduced at high values of m. The two stable states (valley bottoms in the dynamical landscape) are separated by a 'breakpoint' (watershed), indicated by the dashed line in Fig. 2*e*; disturbances severe enough to transgress the breakpoint will carry the system from one state to the other.

These threshold and breakpoint concepts are of obvious importance to epidemiologists concerned with disease eradication[10,27,28].

Of special importance are the effects that can arise from the now widely recognised fact that the impact of an infection is often related to the nutritional state of the host[69–75]. Broadly speaking, malnourished hosts have lowered immunological competence, and are less able to withstand the onslaught of infection[76–78]. The effective pathogenicity of a parasite therefore tends to increase as host density rises to a level where competition for available food resources is severe[79,80]. Given certain reasonable assumptions[35] about the exact relation between pathogenicity (α) and host density (N), two stable states may occur for a given set of rate parameters. The outcome of such a model[35], for a directly transmitted helminth infection, is shown in Fig. 2*d*. Both states reflect stable endemic disease: one equilibrium is characterized by high host density and low worm burdens; the other by low host density (severely depressed by the disease) and high average burdens of parasites. As for the schistosome model of Fig. 2*e*, the two states are separated by a breakpoint or unstable equilibrium.

The discontinuous switch from low to high levels of infection, following a disturbance severe enough to cross the breakpoint, will show up as an apparent 'epidemic' outbreak of disease, typically producing many host deaths. Interestingly, many documented accounts of disease outbreaks are for host populations at high densities, where stress induced by overcrowding or malnutrition is present[71,72]. It is very likely that such outbreaks are to be explained[35] by the alternative stable states produced by close links between pathogenicity and nutrition or stress, rather than by the commonly accepted hypothesis of enhanced transmission with high density populations[81].

Parasitic infections with very complex life cycles may possess more than two stable states, particularly if predator-prey links are involved in the transmission from one host to the next, as is the case for many helminth parasites. There is a desperate paucity of data, from field or laboratory, bearing on these general points.

Conclusion

This two-part article has blended some new theoretical studies and new analysis of existing laboratory data with a review and synthesis of past and present models for the overall transmission dynamics of parasitic infections. We have defined 'parasite' broadly to include viruses, bacteria and protozoans along with the more conventional helminth and arthropod parasites, and we have concentrated attention upon the circumstances under which the infection may significantly alter the growth rate of its host population.

Some of the theoretical conclusions can be pleasingly supported by hard data, while others remain more speculative. On the whole, our main goal is to help elevate the study of host–parasite population dynamics to its proper place in ecological thinking; parasites (broadly defined) are probably at least as important as the more usually-studied predators and insect parasitoids in regulating natural populations.

We are grateful to many people, and particularly to Mary Anderson, David Bradley and James Yorke, for their help. This work was supported in part by the NSF, under grant DEB77-01565.

Radio studies of the double QSO, 0957+561A, B

G. G. Pooley
Mullard Radio Astronomy Observatory, Cavendish Laboratory, Cambridge, UK

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Macclesfield, Cheshire, UK

The radio source 0957+561 has at least four components. Two coincide with the optical QSOs, which is in accordance with the hypothesis that the QSOs are images of a single object due to a gravitational lens. There are details of spectra and structure which are more difficult to reconcile with the hypothesis.

THE pair of QSOs 0957+561A, B have been shown to have remarkably similar optical characteristics by Walsh, Carswell and Weymann[1] and they suggest that the QSOs may be two images of the same object formed by a gravitational lens. The detailed properties of the radio source are clearly of great interest, and we present here a radio map and other observations discussed in the context of a gravitational lens.

Observations

The total flux density of the radio source has been measured at various frequencies summarised in Table 1. The data are consistent with a flux density $S \propto \nu^{-0.65}$. The two observations at λ 6 cm suggest the possibility of variability.

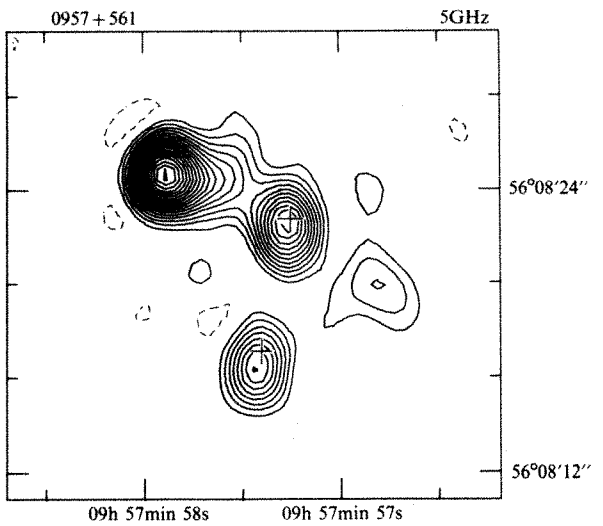

Fig. 1 5-GHz map with 5-km telescope using normal aperture grading. The contour interval is 4 mJy for an unresolved source. Negative contours are shown as dashed lines and the zero contour is omitted. +, Positions of the optical QSOs.

To obtain the 5 GHz map the source was observed with the Cambridge 5-km telescope for three 12-h periods during the period 22–29 May 1979, twice to map the Stokes parameters $I-Q$ and once to map U and Q. The two observations of $I-Q$ show only differences consistent with noise, atmospheric fluctuations, and so on. The mean of the two sets of data is presented in Figs 1 and 2. Figure 1 shows the map produced using the standard truncated gaussian grading function (falling to 0.3 at the largest spacing) with a beamwidth 2″ in RA by 2.4″ in dec. The map in Fig. 2 was produced using uniform aperture grading with a 1.75″×2.11″ beam but rather larger sidelobe responses. Note that the declination scale in Fig. 2 is compressed by sin δ so that the beam appears circular on this projection; this shows more clearly whether components are extended.

The positions, flux densities and angular sizes of the components are summarised in Table 2, which also includes the positions of the optical objects A and B for comparison.

The polarisation observations show no polarised flux >10 mJy, except for component B, which shows a marginally significant value of 11 mJy at position angle 90°.

Observations were made at 408 MHz in April–May 1979 with interferometers consisting of (1) the MK IA telescope of Jodrell Bank and a 25-m telescope at Knockin (67 km south-west of Jodrell Bank), and (2) MK IA and a 25-m telescope at Defford (127 km south of Jodrell Bank). In each case the source was tracked continuously for 24 h. Data were also taken simultaneously on a compact source, 0954+556 (4C55.17) within the primary beam. The latter was used as a reference to reduce phase fluctuations due to the troposphere and ionosphere using the technique described by Peckham[2]. The data were transformed and 'cleaned' to produce a map with a synthesised beam of FWHM 0.9″. The map suffers limitations because of incomplete coverage of the u–v plane, and residual phase fluctuations. In particular, the incomplete coverage means that components extended on a scale ≥4″ will not be detected.

The maximum correlated flux density is 900 mJy, corresponding to a visibility of ~0.6. Details of the various components definitely detected are given in Table 3. The flux densities are subject to a possible scale error of ±25% and a random error of ~50 mJy. At 408 MHz the NE component is the dominant one and its extension is very similar to that seen at 5 GHz. The ratio of the integrated flux densities at these two frequencies has spectral index α_{408}^{5000} of −0.65, similar to the overall spectrum of the source. It is not possible to say whether component W is extended, but again $\alpha_{408}^{5000}=-0.65$ although the error in this value is rather large. The spectrum of component A appears to be significantly flatter than either NE or W. In addition to the components in Table 3, there is a possible component which may be extended ~2″–3″, centred east of component B. There is no definite detection of component B itself.

Observations were also made at 1,612 MHz between MK IA and Knockin and at 1,667 MHz between MK IA and Defford, again for 24 h at each baseline. Because of the narrower primary beam it was not possible to observe 0957+561 and the reference 0954+556 simultaneously. Instead each was observed for alternate 10-min intervals throughout the 24 h. The data were combined into a 'clean' map with a synthesised beam of FWHM 0.2″, and components extended on a scale ≥1″ cannot be detected. The maximum correlated flux density was 190 mJy corresponding to a visibility of the order ~0.4. Because of the poorer signal-to-noise ratio and the inability to observe the reference source simultaneously, the phase fluctuations were worse than at 408 MHz and the map correspondingly degraded. The apparent flux density of components is reduced by an unknown factor. A compact feature with extension <0.2″ was, nevertheless, clearly detected in component A. There were also probably detections of components W and B; both were apparently extended and this makes comparison of flux densities with A very difficult.

Table 1 Spectral data for 0957+561

NE	57.90	24.7	120	~3

Discussion

The structure of 0957+561 is unusually complex, and unlike any other single radio source we know. We consider first the relevance of the observations to the gravitational lens hypothesis. The most important prediction of the theory is that a point object should give rise to point images which have identical spectra apart from possible extinction along the differing paths of propagation. In the case of a point mass causing the gravitational deflection there should be two images, but if an extended mass such as a galaxy causes the deflection, then multiple images are possible (see ref. 3 and references therein). Radio components A and B in Figs 1 and 2 are coincident with the optical objects within the errors of measurement. Like the optical QSOs they are comparable in flux density. However, a detailed comparison of radio and optical properties presents some apparent discrepancies with the theory.

Flux ratio. Walsh *et al.*[1] pointed out that in the blue the flux density of QSO B is ~0.7 that of QSO A but in the red they are

equal. They suggested that a possible cause is extinction by dust at the redshift of the QSO ($z = 1.4$). If so then the intrinsic flux from B should be greater than that from A, the ratio being ~1.5. While this factor is somewhat uncertain, it should definitely be >1 (ref. 4). According to Table 2, the ratio at 5 GHz is ~0.8. If the gravitational lens hypothesis is to accommodate this discrepancy, then (1) the source must vary at either radio or optical wavelengths, or both, or (2) an alternative expanation to the dust hypothesis must be found to account for the optical colour difference. In connection with (1), we note that the two images should follow identical light curves with a relative delay of several months to years depending on the precise geometry of the paths. The two observations at 5 GHz in Table 1 indicate a change in total flux density of 80 ± 35 mJy over 4 yr. While some reservation must be made about this apparent variation because the observations were made by very different techniques, clearly a variation of this magnitude could reconcile the observed flux densities. Changes should be observable in 5 GHz maps fairly quickly, and regular observations are planned for this purpose.

Radio spectral differences. This is an extension of the previous point. The failure to detect component B at 408 MHz suggests the flux ratio (B/A) is ≤ 0.5, which is less than that at 5 GHz or in the optical region. Again, in principle, this could be accounted for by differences in variation at different frequencies; indeed, variable radio sources do in fact normally show differences in the pattern of variation at different frequencies. However, variation of this magnitude at 408 MHz is very unusual. The errors in the 408 MHz data at present require this point to be treated with caution, but if further observations confirm it then it may be difficult to sustain the gravitational lens hypothesis. We hope to make improved long-baseline observations at 408 MHz shortly.

Extension of the components. Figure 2 suggests that component A is <1″ in extent but B is extended ~1.5″ along the line joining A and B. This is incompatible with the simple picture of two images of a point object. We may be seeing unresolved multiple images produced because the mass causing the deflection is extended. The direction of extension is as expected for such an effect. The optical image should then also be extended; available observations do not enable this to be seen. Higher resolution observations at both radio and optical wavelengths would clearly be desirable.

So far we have considered only the components A and B close to the optical QSOs. We now consider the components NE and W. Suppose we are in fact seeing images formed by a gravitational lens. Where are the true positions of the 'objects' and where are the second images? Figure 3 shows a possible geometry based purely on the radio observations.

The theory of image formation by a point deflecting mass can be found in, for example, Refsdal[5] and Press and Gunn[6]. Here we quote some results which are useful in interpreting observations and for constructions such as Fig. 3. On the celestial sphere, let M be the projection of the deflecting mass and O the projection of the 'true' position of a point object (the position in the absence of M). Then point images O′, O″ are formed on the extension of the line OM; the former is on the opposite side of O from M, the latter on the opposite side of M from O. Let the angles MO, MO′, MO″ and O′O″ be β, α_1, α_2 and α respectively. Clearly, $\alpha = \alpha_1 + \alpha_2$. Then the following relations hold:

Flux ratio of O′ and O″ $= F'/F'' = \alpha_1^2/\alpha_2^2$

$$4\alpha_1\alpha_2 = \alpha^2 - \beta^2 = \alpha_0^2 = \text{constant independent of data}$$

$$\alpha_1 = \alpha_2 + \beta$$

The flux ratio and angular separation of A and B with these equations enable Fig. 3 to be constructed.

The second images of components NE and W are in fact too faint to be detected as separate components (less than 1 contour on Fig. 1). Note that they lie in the region of the northwards extension of component B, which may provide an alternative explanation of the extension. The true source then consists of three components: a flat spectrum one giving rise to images A and B (and the optical images) and two steep spectrum ones giving rise to images NE and W. Three-component structure of radio sources is quite common with a flat spectrum object coincident with the optical object and two steep spectrum lobes on opposite sides. In Fig. 3 the true position of the flat spectrum component is not on the line joining the two steep spectrum components. However, though unusual, this configuration is by no means unknown, see for example 3C270.1 and 3C275.1 (ref. 7).

If we are not seeing the result of a gravitational lens, then since component A lies on the line joining NE and W it is likely that these three components constitute a single radio source of a common type. Then we must assume component B is independently a radio source of very nearly the same flux density as A. This then adds another coincidence to those of the emission spectra and absorption spectra described by Walsh *et al.*[1] and by Weymann *et al.*[8].

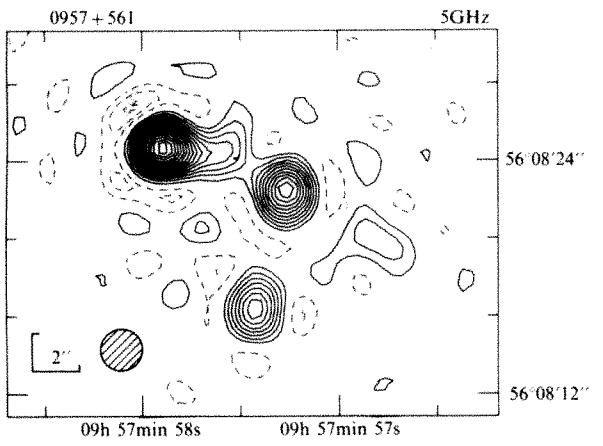

Fig. 2 5-GHz map with uniform aperture grading and declination scale compressed by sin δ.

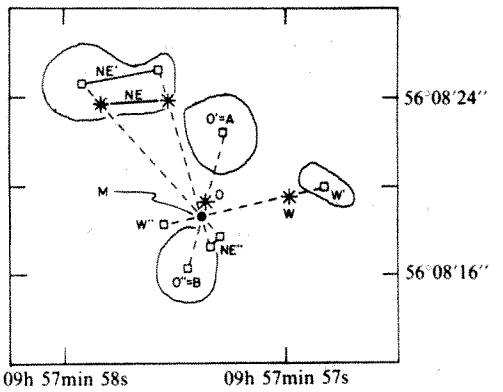

Fig. 3 Possible geometry of the source and image formed by gravitational lens. M is a point deflecting mass; W, O and NE are true positions of 'object' components; W′, W″, O′ = A, O″ = B and NE′, NE″ are the images. The position of M is determined purely from the radio flux density ratio of components A and B.

Table 3 Details of components detected at 408 MHz

Component	RA	Dec (1950.0)	Flux density (mJy)	Size (arc s)
W	09 h 57 min 56.7 s	+56° 08′ 19″	140	—
A	57.36	22.6	120	—
NE	57.89	24.9	600	3

Finally on the gravitational lens hypothesis we consider the possibility that the massive object causing the deflection is itself a radio source. While the mass required depends on the distance of the object, it is likely to be in the range of the most massive elliptical galaxies. Statistics are very sparse for such objects, but using the bivariate luminosity function of Auriemma *et al.*[9] as a guide, the probability that the galaxy may have an associated radio source of flux density 25 mJy at 5 GHz is ~0.005. Thus it is unlikely that either component W or NE is associated with the lens itself.

Conclusions

The most important feature of the radio data is that there are radio components coincident with the optical QSOs and with comparable flux density at 5 GHz where the structure is best determined. This is consistent with the gravitational lens hypothesis, which would have been ruled out if, for example, only one QSO had a coincident radio source. However, there are details which may or may not be reconciled with the hypothesis. More stringent tests, the most crucial being to study the variations of flux from A and B, must now be made to distinguish between the gravitational lens and other hypotheses.

We thank Tim Cornwell and Peter Wilkinson for assistance with data reduction.

The amino acid sequence of the α-chain of human fibrinogen

R. F. Doolittle, K. W. K. Watt, B. A. Cottrell, D. D. Strong & M. Riley

Department of Chemistry, University of California, San Diego, La Jolla, California, 92093

The amino acid sequence of the human fibrinogen α-chain reveals a structure that can be divided into three zones of unique amino acid composition. The middle of these contains the two primary α-chain cross-linking acceptor sites and consists of a remarkable series of internal duplications.

THE α-chain is the largest of the three non-identical chains that compose the human fibrinogen molecule $(\alpha_2 \beta_2 \gamma_2)$[1]. It contains 610 residues and has a calculated molecular weight of 66,125. Unlike the β- and γ-chains, it does not contain covalently bound carbohydrate[2,3]. More than 90% of the α-chain amino acid sequence has previously been reported[4–10]. In this article we report the complete amino acid sequence (Fig. 1) and comment on a variety of structural and evolutionary features revealed by these determinations. The completion of the sequence was accomplished by the isolation of an 84-residue peptide from a staphylococcal protease digest of the largest α-chain cyanogen bromide fragment. A summary of the data used to obtain the sequence is depicted in Fig. 2.

Distribution of amino acids

A linear residue-by-residue plot of the amino acid sequence of the human fibrinogen α-chain indicates that the structure can be divided into three distinct zones of approximately 200 residues, each of which is readily distinguishable on the basis of amino acid composition alone (Fig. 3). We do not know whether these zones are equivalent to independently folding domains. The regions are designated ZN, ZM and ZC and correspond roughly to the amino-terminal third (ZN), the middle third (ZM), and the carboxy-terminal third (ZC), respectively. A short interzonal sequence between zones ZN and ZM has been designated IZ (Fig. 4). In zone ZN, the first 194 residues from the amino-terminus, the amino acid composition is well balanced except for a very long proline-free stretch and a notable deficiency of glycine residues. This part of the α-chain is linked to the β- and γ-chains by two sets of unique six-cysteine combinations which we have called disulphide rings[11]. The regions between these delineating rings are thought to be three-stranded compound α-helices of the sort known as coiled coils[11]. Indeed, computer-generated conformational prediction schemes[12] indicate that virtually all the α-helical content of the α-chain occurs in zone ZN (Fig. 4).

Zone ZM (middle section) is composed of residues 240–424. More than half the 185 residues in this section are glycine, serine, proline or threonine, and, with the exception of tryptophan, there are few amino acids with nonpolar side chains. The tryptophan exception is extraordinary in that 7 of the α-chain's 10 tryptophan residues occur in this otherwise

© Macmillan Journals Ltd 1979

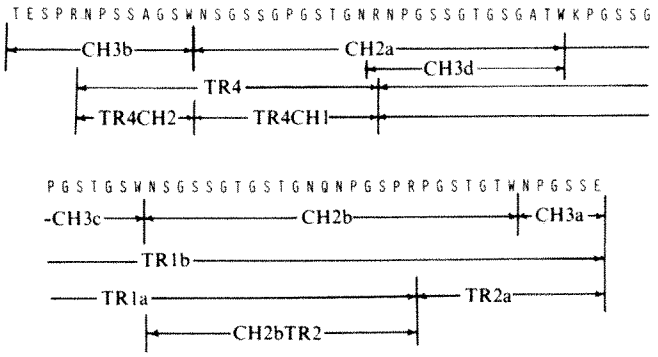

Fig. 2 Summary of data used to deduce the sequence of an 84-residue peptide isolated from a staphylococcal protease digest of the largest α-chain cyanogen bromide fragment. TR = trypsin; CH = chymotrypsin. The sequences of the various subpeptides were determined by procedures reported in our earlier papers. Full experimental details will be presented elsewhere.

exceedingly polar zone. Moreover, the tryptophan residues occur with a definite periodicity reflecting an extended series of 13-residue homology repeats (Fig. 5). The homology repeats, which can also be depicted as a set of 39-residue duplications, have been evaluated by the computer conformation programs and assessed as being predominantly random coil with some contribution from reverse turns. A prototype sequence, derived from a count of the most frequent residues at each position of the 13-residue segments, was also evaluated and found to be a random coil with regularly interspersed turns (Fig. 5).

The carboxy-terminal zone (ZC; residues 425–610) is also rich in serine, threonine and glycine, but in addition, this section contains a large number of amino acids with nonpolar side chains. Although there are no tryptophan residues, more than a quarter of the 186 residues are categorised as nonpolar. A single interchain disulphide loop connects residues 442 and 472. As in the case of ZM, the major conformational prediction is for random coil, although a short segment of α-helix is predicted for the region 583–591.

Distribution of charges

Approximately one-quarter of the α-chain's 610 residues are charged at neutral *p*H, the net charge being about +6 (Table 1). This net positive charge is partly offset by the fractional occurrence of phosphoserine residues that have not been included in the estimate. Moreover, each of the major zones is effectively neutral, compensating numbers of positive and negative charges being present throughout. An exception occurs in the 45-residue interzonal segment IZ, where basic residues (neglecting the single histidine) outnumber acidic residues by eight to three. Zone ZM is not only effectively neutral, but it also bears fewer charges generally than the other two major segments; only one-sixth of its side chains are charged at neutral *p*H (Table 1).

Although we have commented on the general charge distribution of the entire fibrinogen molecule elsewhere[13], it is useful to summarise some of those observations here (Table 2). Thus, the net charge on the three non-identical chains from fibrinogen as estimated from their amino acid sequences is in complete agreement with their observed behaviour on CM-cellulose chromatography, the most negatively charged γ-chain eluting first, followed by the β-chain, which is less negative, and finally, by the α-chain with its net positive charge. Moreover, the sum of the estimates (Table 2) indicates that at *p*H 7.3 the parent fibrinogen molecule bears a net charge of about −20. When considered domain by domain, it seems that almost half of this negativity is localised in the central domain (net charge −8) and that a charge reversal occurs centrally on removal of the two pairs of negatively charged fibrinopeptides (A and B) by thrombin. The terminal domains (compare fragments D) are also negative (−4 each), whereas the combined α-chain protuberances (ZM and ZC) are only very slightly negative (−1 each).

Susceptibility to proteases

The susceptibility of the α-chain to proteases—especially as the chain exists in the native fibrinogen molecule—provides certain insights into its domainal structure. In particular, the 45-residue

Table 1 Distribution of charges in α-chain by zone

Zone	Residues	Lys Arg	His	Glu Asp	Approximate net charge*	% Charged residues
ZN	1–194	33	3	32	+2	(34%)
IZ	195–239	8	1	3	+5	(24%)
ZM	240–424	15	3	16	0	(16%)
ZC	425–610	23	8	26	−1	(27%)
Total chain	1–610	79	15	77	(+5)	(26%)

*Calculated for *p*H 7.3; histidine *p*K taken as 6.7. The estimate does not include contributions from fractionally occurring phosphoserines.

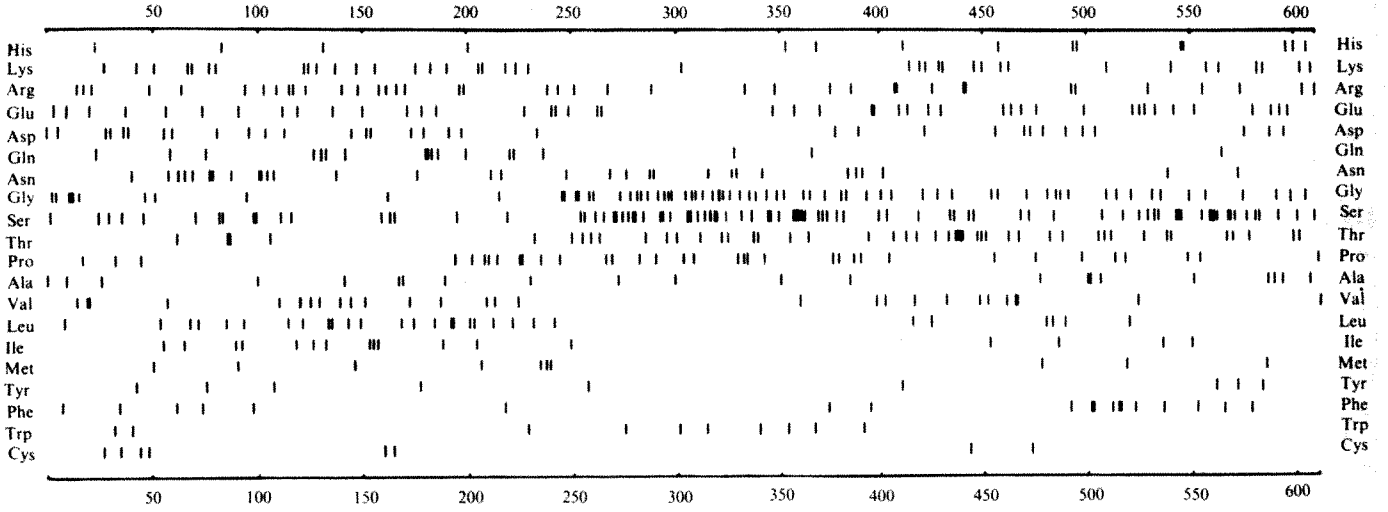

Fig. 3 Distribution of amino acids in the α-chain of human fibrinogen showing how composition changes radically from one end of the chain to the other. Zone N (amino-terminal) includes residues 1–194. The distribution of amino acids is fairly even except for the marked deficiency of proline and glycine. It is separated from the next major sector by a connecting segment (IZ = 195–245) that is rich in proline and exceedingly susceptible to proteolytic excision. Zone M (middle) extends from residues 246 to about 410. More than half the residues in this section are glycine, serine, proline or threonine, but it also contains seven tryptophan residues. The section contains only two glutaminyl side chains, both of which are cross-linking acceptor sites. The third sector (ZC) begins at about residue 411 and extends to the carboxy-terminus.

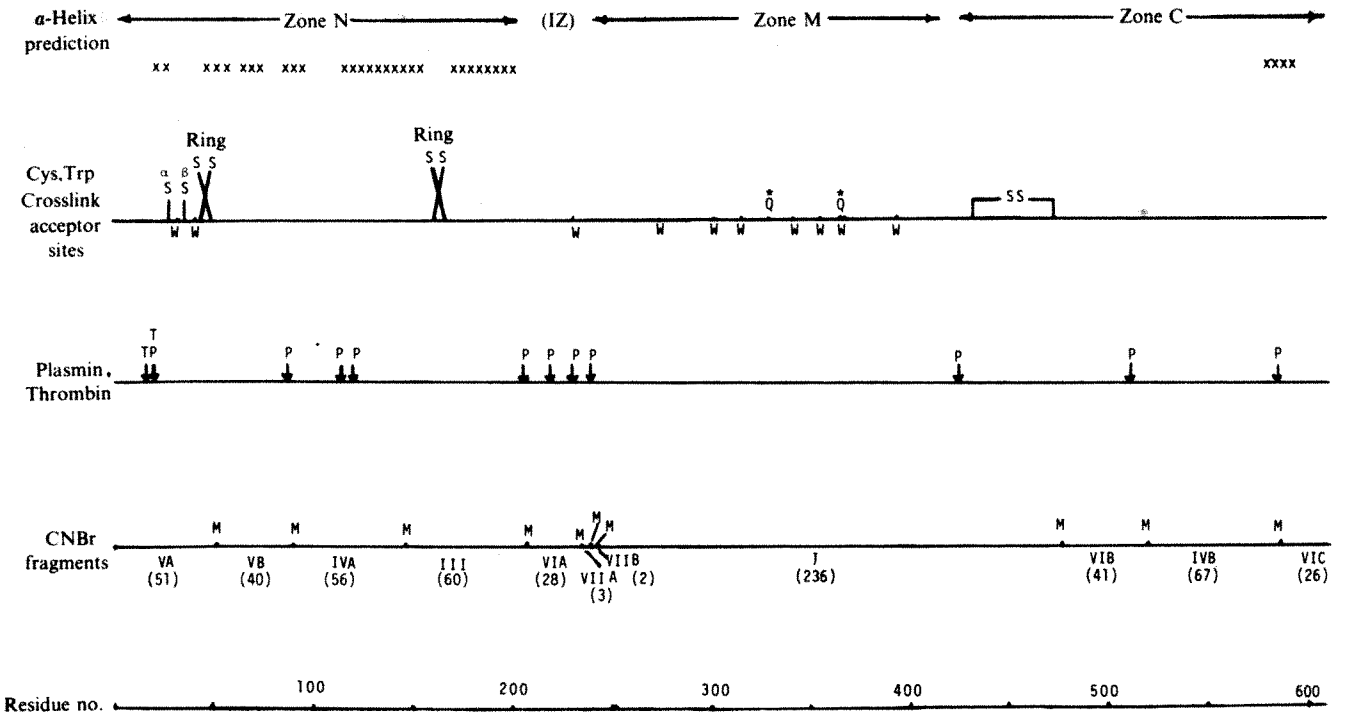

Fig. 4 Schematic representation of human fibrinogen α-chain showing thrombin attack point in releasing fibrinopeptide A(T), principal plasmin attack points (P), cross-linking sites (Q̊), 10 tryptophan residues (W) and 8 cysteine residues (C). Also shown are the 11 peptides produced by cyanogen bromide cleavage at the 10 methionine residues (M). Regions of computer-predicted α-helix are denoted by ××××.

interzonal (IZ) stretch from residues 195 to 239 includes four plasmin attack points[5]. This short segment contains eight proline residues which reflect the radical change in amino acid composition at this junction and mark the end of the long α-helical section that extends through most of ZN. Its net positive charge (Table 1) may also be a factor in its susceptibility to plasmin. The same region is apparently attacked by several proteases other than plasmin, as evidenced by the fact that digestion of fibrinogen (or fibrin) by a variety of enzymes leads to similar sets of early digestion products, at least on a gross level[14]. This kind of substrate-directed vulnerability indicates that the interzonal segment is exposed and accessible.

A second major attack region for plasmin occurs in the middle of the 'coiled-coil' region. The α-chain, in common with the β- and γ-chains (Fig. 6), is broken at several lysine and arginine residues in this region to give rise (ultimately) to the core fragments known as fragments D and E (ref. 15)

Plasmin also attacks the α-chain and/or its largest cyanogen bromide fragment, CNI (Fig. 4), at a point (Arg 424) separating ZM and ZC. Several other plasmin cleavages also occur, both in the native fibrinogen molecule and in the reduced and alkylated α-chain, especially near the ends of the chain. Finally, as is well known, thrombin triggers the polymerisation of fibrinogen to yield fibrin by cleaving the arginyl-glycine bond at α16–17, thereby releasing the fibrinopeptide A and exposing the Gly-Pro-Arg sequence at residues α17–19 which is apparently essential for polymerisation.

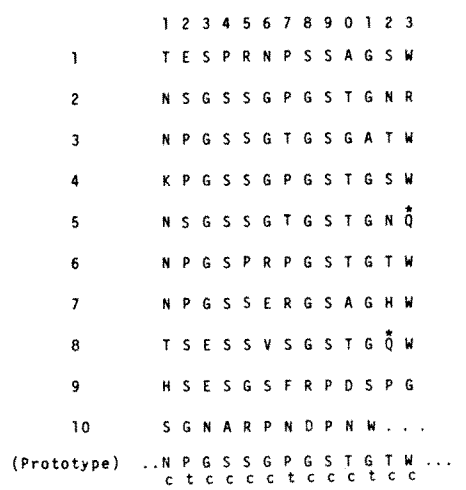

Fig. 5 Amino acid sequence of a section from zone M showing 13-residue homology repeat that occurs 10 times in tandem. A prototype sequence is shown at the bottom together with a computer-derived structural prediction for each residue (c = random coil; t = reverse turn). Asterisks denote cross-link acceptor sites.

Other functional considerations

α-Chain cross-linking: Although the first stages of fibrin polymerisation do not involve covalent bonds, the polymer is subsequently reinforced ('stabilised') by the introduction of intermolecular γ-glutamyl-ε-lysine peptide bonds. The formation of these covalent bonds between side chains is catalysed by the transglutaminase known as factor XIII. The first of these bonds formed involves γ-chains exclusively, a set of reciprocal linkages being formed intermolecularly between abutting γ-chains in the polymer, which, on reduction and dissociation of the parent fibrin(ogen) molecules, gives rise to 'γ–γ dimers' (ref.

Table 2 Distribution of charges on human fibrinogen by chain*

Chain	Lys Arg	His	Glu Asp	Sialic acid	Phospho-serine	Approximate net charge‡
α-Chain	79	15	77	0	1†	+5
β-Chain	58	7	61	2	0	−5
γ-Chain	44	10	54	2	0	−10

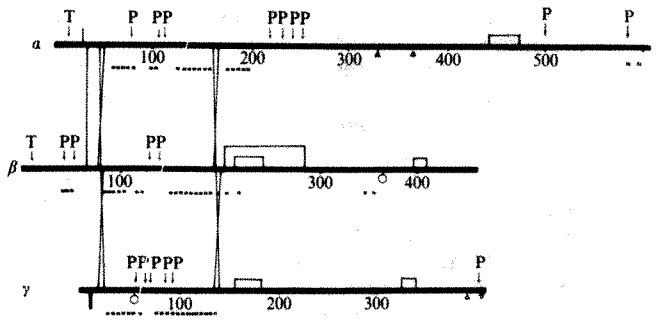

Fig. 6 Schematic depiction of three non-identical chains of human fibrinogen showing disulphide connections, carbohydrate attachment sites (◇), thrombin (T) and plasmin (P) attack points, cross-linking sites (△ and ▽) and computer-predicted helical regions (≈ ≈ ≈).

16). In a significantly slower involvement, α-chains can also be cross-linked by factor XIII, the bonding in this case leading to extended interchain involvements referred to as α-chain multimers[17]. However, the overall geometry and arrangement of these multimeric arrays has been unclear. We can now report the exact position of those α-chain glutamine residues that incorporate radioactive substitute donors (^{14}C-glycine ethyl-ester) under the influence of activated factor XIII. Thus, glutamines α328 and α366, both of which occur in ZM, are the only acceptor sites for the substitute donor. Significantly, however, they are also the only glutamine residues in ZM, thus raising the question of whether the specificity is narrow because there are only two glutamine residues or vice versa, an evolutionary exclusion of glutamine residues being required to maintain the ordered cross-linking of these randomly disposed segments. Furthermore, there is only a single glutamine residue in the carboxyl-terminal zone ZC (Gln 563), and it was devoid of radioactivity; nor were any of the 15 glutamine residues in ZN and IZ labelled. Furthermore, in neither Gln 328 nor Gln 366 does the surrounding sequence bear any resemblance to the γ-chain cross-linking acceptor site[16].

Other α-chain involvements: Fibrinogen is widely known to interact with certain other plasma proteins and particles, including associations with fibronectin ('cold-insoluble globulin')[18,19], platelets[20] and certain strains of staphylococcal bacteria[21]. These interactions are thought to involve the carboxyl two-thirds of α-chains, evidence for this including the observation that plasmic digestion of fibrinogen removes those regions concomitant with a loss of interaction[22–24].

During our determination of the α-chain structure we developed a procedure for isolating a soluble fragment corresponding to residues 241–424 ($n = 184$ residues). This fragment, which is a plasmic digestion product of the cyanogen bromide fragment CNI, includes both cross-linking acceptor sites. It also contains two tyrosine residues which can be iodinated. Thus, the fragment should prove very useful in pinpointing many of the extramolecular involvements cited above.

The α-chain protuberance comprised of ZM and ZC also affects other aspects of fibrinogen–fibrin behaviour. It is well known, for example, that fibrinogen 'sticks' to most non-biological materials, including the plastics used in most circulatory-assistance devices. It is possible that this is the result of exposing the tryptophan residues that are normally 'caged' by the repetitive Pro-Gly-Ser-Thr combinations. Also, these portions of the protein are very accessible to cross-linking agents and other types of chemical derivatisation[25]. Furthermore, it has so far not been possible to crystallise mammalian fibrinogens until portions of the α-chain have been digested away[26]. Finally, high-solubility fibrinogen preparations seem to lack these regions of the α-chain.[27]

Fig. 7 Comparison of α-chain amino acid sequence with sequences of β- and γ-chains[31–37] showing significant homology among all three chains over the course of the first 210 residues, but a loss of homology in the α-chain thereafter. The 'best match' leaves a gap throughout most of zone M, some faint resemblance between the α-chain and the other two chains apparently resuming near the carboxyl-terminal segment. Other equivalent alignments are possible, however. As previously noted, the β- and γ-chains are strongly homologous over the course of their carboxy-terminal two-thirds. Matched identical residues are underlined.

Evolutionary significance

The α-, β- and γ-chains of fibrinogen are all equivalently homologous in the region spanned by ZN[28]. Thus, all three chains have two characteristic Cys-X-X-X-Cys sequences spaced appropriately for participation in the two sets of disulphide rings (Fig. 6). Also, both the α- and β-chains have thrombin-sensitive sites near their amino-termini that give rise to the fibrinopeptides A and B, respectively (Fig. 6). Shortly beyond the beginning of ZM, however, the resemblance between the α-chain and the β- and γ-chains abruptly disappears. In contrast, beyond that point the β- and the γ-chains display increasing homology[29,30]. Figure 7 shows a computer-assisted alignment of the three chains. Other reasonable alignments are possible, however, including one in which the carboxyl-terminal segments of the α- and γ-chains are directly aligned.

Given that the prototype fibrinogen molecule originated from two pairs of three identical chains, the question arises, did the β- and γ-chains lose the equivalent of zone ZM, or did it evolve in the α-chain by a more recent set of tandem duplication? In either event, the strong homology between the β- and γ-chain carboxyl-terminal segments suggests that these two chains shared a common ancestor more recently than either did with the α-chain. Moreover, the radical differences in the nature of the various α-chain zones suggests the occurrence of events other than simple gene duplication in the evolution of the α-chain. It is possible that gene splicing was involved, although we know of no other protein with a composition comparable to ZM that might be a candidate for insertion.

The International Committee on Blood Coagulation Nomenclature prefers the convention $A\alpha_2B\beta_2\gamma_2$ as a description of the six chains in the fibrinogen molecule.

The membrane attachment protein for spectrin is associated with band 3 in human erythrocyte membranes

Vann Bennett & Peter J. Stenbuck

Department of Molecular Biology, The Wellcome Research Laboratories, Research Triangle Park, North Carolina 27709

Ankyrin, the membrane attachment protein for human erythrocyte spectrin, is tightly linked in a 1:1 molar ratio with band 3 in detergent extracts of spectrin-depleted membranes. Ankyrin-linked band 3, which represents 10–15% of the total band 3, spans the membrane, and is nearly identical to the major band 3 by peptide analysis. Spectrin binds to solubilised ankyrin-linked band 3, but not to free band 3. A portion of band 3 remains firmly associated with detergent-extracted cytoskeletal proteins. It is concluded that a fraction of band 3 is attached to the erythrocyte cytoskeleton through association with ankyrin, which in turn is bound to spectrin.

EXTENSIONS of the fluid mosaic model for membranes[1,2] have proposed a direct association between membrane-spanning cell-surface proteins and cytoplasmic structural proteins on the inner surface of the plasma membrane[3,4]. These protein interactions may be key events in complex cellular phenomena such as the capping of surface molecules by lymphocytes[5], redistribution and internalisation of receptors for hormones[6] and low-density lipoprotein[7], cell motility[8] and attachment of cells to surfaces[9]. Evidence has been presented for binding of actin[10,11] and intermediate filament protein[12] to cell-surface proteins. However, there is little detailed knowledge of the polypeptides involved in these linkages or of the mechanisms which regulate such interactions. The human erythrocyte provides an experimentally accessible model system for examining protein–membrane interactions at a molecular level. The shape and elasticity of red cell membranes[13,14] and the distribution of intramembrane particles[15] and glycoproteins[16] are controlled by proteins arranged in a cytoskeletal network on the inner surface of the membrane. Direct analysis of the components involved in these phenomena can be achieved, in principle, by measuring reassociation of purified cytoplasmic proteins with acceptor sites exposed on inverted membrane vesicles. This approach has been used to examine the membrane attachment site for human erythrocyte spectrin, which is the major protein in the red cell cytoskeleton.

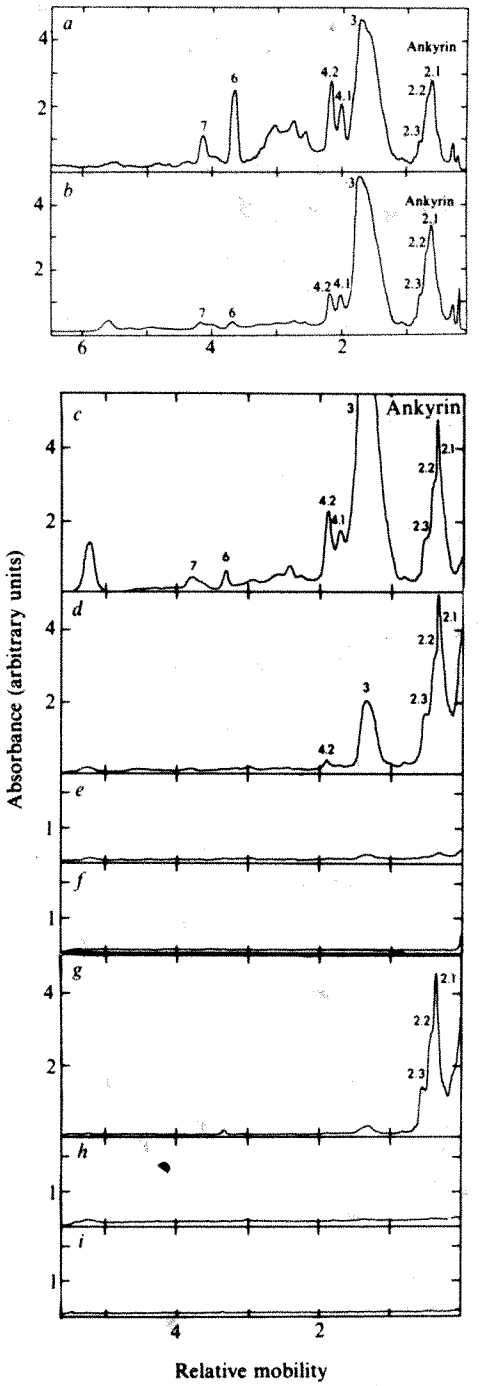

Fig. 1 Isolation of ankyrin-associated proteins by immunoadsorption with anti-ankyrin IgG of Triton X-100-solubilised spectrin-depleted vesicles labelled with [^{125}I]-Bolton Hunter reagent. Spectrin-depleted inverted vesicles[18] from 1-ml erythrocyte ghosts were reacted with 2 mCi [^{125}I]-Bolton Hunter reagent (1,500 Ci mmol^{-1}, NEN) in 0.2 ml 7.5 mM sodium phosphate, *p*H 7.5, for 60 min at 0 °C. The labelled vesicles (1.1 mCi incorporated) were washed, extracted (15 min, 24 °C) with 1.2 ml 7.5 mM sodium phosphate, *p*H 7.5, 1 mM NaEDTA, 0.2 mM dithiothreitol, 10 μg ml^{-1} phenylmethylsulphonyl fluoride and 2% (v/v) Triton X-100, and pelleted (30 min, 250,000*g* at 2 °C). The supernatant was made 0.1 M in KCl, and 10-μl aliquots were either denatured with an equal volume of 1% (w/v) SDS (30 min, 37 °C) or untreated. These samples were incubated (90 min, 0 °C) in 0.3 ml buffer containing 250 μg ml^{-1} bovine serum albumin, 2.5 μg ml^{-1} pancreatic trypsin inhibitor, 100 mM NaCl, 10 mM sodium phosphate, *p*H 7.5, 1 mM NaEDTA, 0.2% Triton X-100, 0.25 μl protein A-bearing fromalin-fixed staphylococci (Calbiochem) and either 2.5 μg affinity-purified anti-ankyrin IgG[20] or 2.5 μg preimmune IgG, and in two tubes 15 μg of the spectrin-binding fragment of ankyrin[19]. The reaction was stopped by addition of 3.5 ml 2 M urea, 1% Triton X-100 and 0.1 M glycine, and the bacteria collected by centrifugation (15 min, 4,000*g*). The bacteria with adsorbed immune complexes were resuspended with 0.1 ml 1% SDS, 40 mM dithiothreitol, 10 mM Tris HCl, *p*H 8, and 1 mM NaEDTA, and 20-μl portions analysed by SDS electrophoresis on a 1.5-mm thick 7.5% polyacrylamide slab gel[49]. The gel was stained with Coomassie blue, dried and developed by autoradiography (bottom panel). The detergent extract used for immunoadsorption was diluted to an equivalent volume to that of the precipitates for analysis. Spectrin-depleted everted vesicles used in this experiment were also electrophoresed, and the gels stained with Coomassie blue and visualised by autoradiography. *a*, Coomassie blue stained; *b* ^{125}I-labelled; *c*, Triton X-100 extract; *d*, immunoprecipitated extract + anti-ankyrin; *e*, extract + ankyrin fragment + anti-ankyrin; *f*, extract + preimmune IgG; *g*, immunoprecipitated SDS-denatured extract + anti-ankyrin; *h*, SDS-denatured extract + ankyrin fragment + anti-ankyrin; *i*, SDS-denatured extract + preimmune IgG.

Spectrin has been radiolabelled with $^{32}P_i$ in intact erythrocytes and purified as an 8S dimer which can recombine with inverted vesicles depleted of spectrin and actin[17]. ^{32}P-Spectrin binds to vesicles with a K_D of 10^{-7}–10^{-8} M, binding to a single class of protein sites tightly bound to the inner surface of the membrane, and present in about 10^5 copies per cell[18]. A water-soluble, 72,000-molecular weight (MW) fragment of the attachment protein is released by mild proteolysis of inverted vesicles, and this polypeptide has been isolated and characterised[19]. The purified attachment fragment binds to spectrin with a 1 : 1 molar ratio, and competes for reassociation of spectrin with vesicles[19]. A 200,000-MW protein localised on the cytoplasmic membrane surface has been identified as the precursor of the spectrin-binding fragment, on the basis of cross-reactivity with monospecific anti-fragment IgG (ref. 20) and by peptide mapping[21]. This protein, which has been named ankyrin, has been partially purified and found to bind to spectrin as well as competitively inhibiting reassociation of spectrin with the membrane[20].

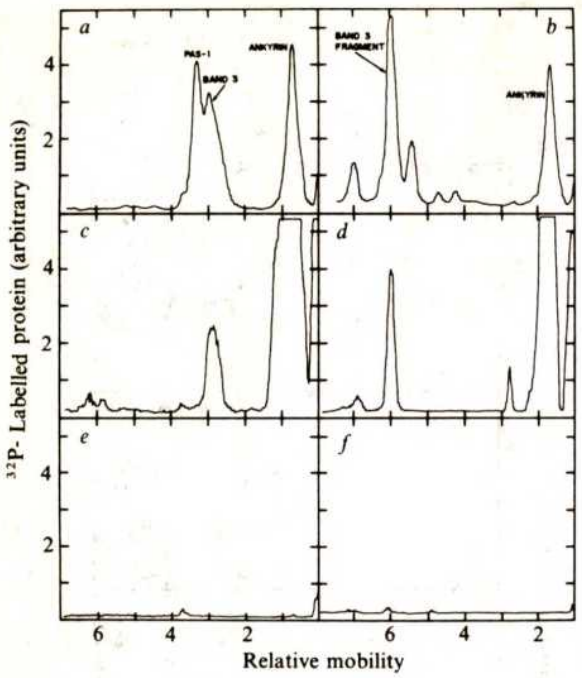
Ankyrin dissociates from the membrane following treatment with dilute acid[20], and thus is not an integral membrane protein. It probably does interact with such proteins, as the lateral mobility of fluorescence-labelled integral proteins is increased by incubation of erythrocyte ghosts with the spectrin-binding fragment of ankyrin[22]. This report demonstrates association of ankyrin with band 3, the major membrane-spanning polypeptide of the erythrocyte membrane[23–25].

Identification of ankyrin-associated polypeptides

Ankyrin-associated polypeptides were isolated from Triton X-100-solubilised, spectrin-depleted vesicles by immunoadsorption with monospecific anti-ankyrin IgG. The antiserum was raised against the 72,000-MW spectrin-binding fragment of ankyrin which had been isolated by SDS-polyacrylamide gel electrophoresis (PAGE), and ankyrin-specific IgG was purified by affinity chromatography with immobilised fragment[20]. The immune complexes formed between anti-ankyrin and the membrane proteins were isolated with formalin-fixed protein A-bearing staphylococci, which bind with high affinity to the Fc portion of IgG[26]. The bacteria were subsequently washed with 2 M urea and 1% Triton X-100 to minimise nonspecific interactions. It should be emphasised that only proteins that are tightly associated and unaffected by Triton X-100 will be detected by this procedure.

Membrane polypeptides were analysed in nanogramme amounts without interference from immunoglobulin chains by labelling vesicles with ^{125}I-labelled Bolton Hunter reagent. This reaction is achieved in mild conditions, and radiolabels identical polypeptides as visualised by staining with Coomassie blue. Band 3 and ankyrin (bands 2.1, 2.2, 2.3) are labelled in nearly the same relative intensity, although other polypeptides are labelled to a lesser extent by the Bolton Hunter reagent (Fig. 1).

Immunoadsorption of solubilised vesicles with anti-ankyrin IgG resulted in binding of essentially all the 200,000-MW polypeptide (ankyrin) and of polypeptides of ~180,000 and 190,000 MW (bands 2.3 and 2.2) which are proteolytic fragments of ankyrin[20,27]. In addition, the immunoprecipitate



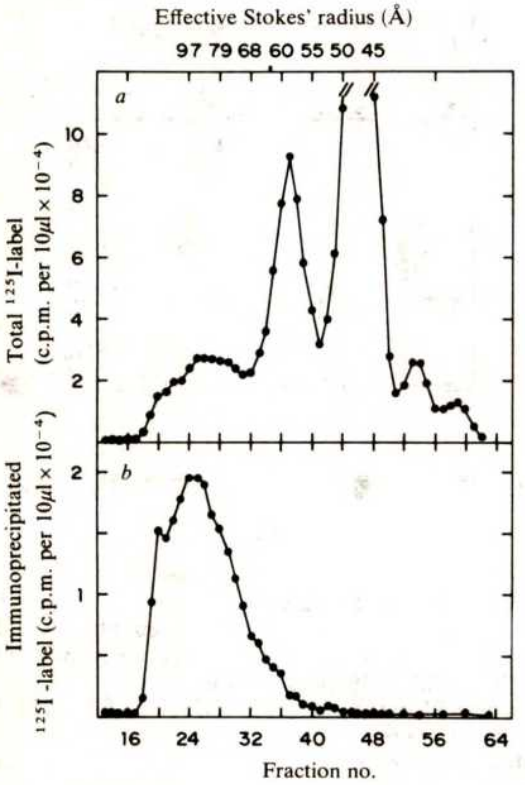


Fig. 2 Immunoadsorption with anti-ankyrin IgG of Triton X-100-solubilised spectrin-depleted vesicles from ^{32}P-labelled erythrocytes that were untreated or externally digested with α-chymotrypsin. Packed erythrocytes (3 ml) were incubated for 150 min at 37 °C in the presence or absence of 100 μg ml^{-1} α-chymotrypsin (70 U per mg) in 20 ml of Krebs–Ringer bicarbonate buffer supplemented with 200 U ml^{-1} penicillin G and 10 mM D-glucose. The cells were washed three times in 0.15 M NaCl, and then labelled with $^{32}P_i$ during a 15-h incubation at 37 °C in 5 ml of buffer containing 135 mM NaCl, 20 mM $NaHCO_3$, 4 mM KCl, 2.5 mM $MgCl_2$, 1 mM $CaCl_2$, 10 mM D-glucose, 1 mM adenosine, 200 U ml^{-1} pencillin G, 50 μg ml^{-1} phenylmethylsulphonyl fluoride and 0.5 mM [^{32}P]$NaPO_4$ (4 Ci mmol^{-1}, NEN), *p*H 7.5. Spectrin-depleted inverted vesicles were prepared from the ^{32}P-labelled cells[18], which were solubilised, immunoadsorbed and analysed as described in Fig. 1. The data are presented as densitometer scans of the portions of autoradiograms corresponding to MWs greater than 50,000. Band 3 and band 3 fragment were identified by comparison with the Coomassie blue-stained gels. *a*, Undigested ^{32}P-labelled vesicles, Triton X-100 extract; *b*, externally digested ^{32}P-labelled vesicles, Triton X-100 extract; *c*, immunoprecipitate of undigested extract + anti-ankyrin; *d*, immunoprecipitate of externally digested extract + anti-ankyrin; *e*, immunoprecipitate of undigested extract + ankyrin fragment + anti-ankyrin; *f*, immunoprecipitate of externally digested extract + ankyrin fragment + anti-ankyrin.

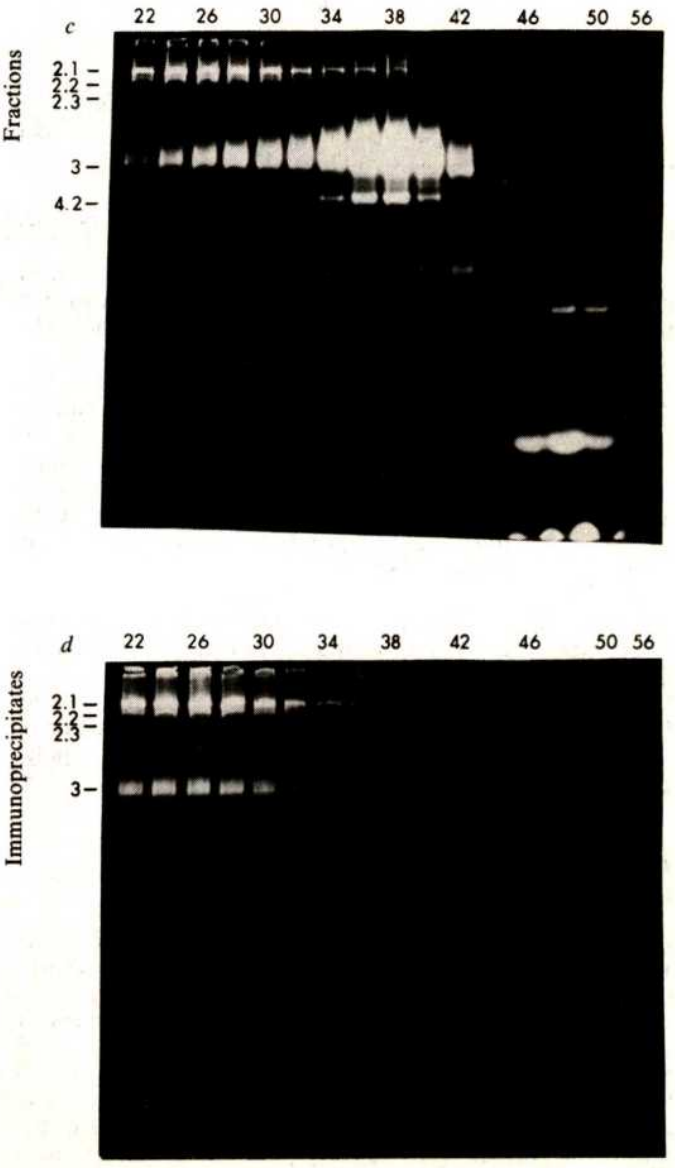

Fig. 3 Ultrogel AcA22 chromatography of Triton X-100-solubilised spectrin-depleted vesicles labelled with [^{125}I]-Bolton Hunter reagent. Vesicles were labelled and solubilised (Fig. 1) and a 0.7-ml sample chromatographed at 4 °C on a column (1.0 × 60 cm) packed with Ultrogel AcA22 (LKB) and equilibrated with 100 mM KCl, 10 mM $NaPO_4$, *p*H 7.5, 1 mM NaEDTA, 1 mM NaN_3, 0.2 mM dithiothreitol and 0.2% Triton X-100. Fractions (0.8 ml) were assayed for total radioactivity (*a*) and for immunoprecipitable radioactivity using anti-ankyrin fragment IgG as in Fig. 1 (*b*). Pooled fractions (*c*) and the corresponding immunoprecipitates (*d*) were also analysed by SDS electrophoresis. The column was calibrated with rabbit muscle glyceraldehyde-3-phosphate dehydrogenase (44 Å) bovine liver catalase (52 Å), horse spleen ferritin (59 Å) and human IgM (120 Å).

exhibited a diffusely staining band of ~95,000 MW, which contains about 15% of the band 3 material, and a 72,000-MW polypeptide (band 4.2) (Fig. 1). Polypeptides of 28,000 MW (band 7) and 17,000 MW (band 8) were also present, but in smaller amounts which are not well visualised in these experiments. Glycophorin (PAS-1) was not clearly labelled, but was apparent in membranes from erythrocytes incubated with $^{32}P_i$ (ref. 28) (Fig. 2), and following periodate oxidation and tritiation with [^{3}H]$NaBH_4$. ^{32}P-Glycophorin was not immunoprecipitated (Fig. 2), and the same result was obtained with the tritium-labelled protein (not shown).

Several lines of evidence demonstrate that the polypeptides immunoprecipitated by anti-ankyrin IgG were associated with ankyrin, and were not nonspecifically adsorbed or bound directly to the antibody. Unlabelled ankyrin fragment blocked binding of ankyrin as well as of band 3 and the other polypeptides (Fig. 1). Immunoadsorption of solubilised vesicles previously denatured with SDS yielded only ankyrin (bands 2.1, 2.2, 2.3), with no band 3 or band 4.2, and this interaction was also blocked by the ankyrin fragment (Fig. 1). Preimmune IgG precipitated no polypeptides from either denatured or untreated vesicle extracts (Fig. 1). Finally, bands 3 and 4.2, which had been separated from ankyrin by gel filtration (see below), did not cross-react with anti-ankyrin IgG.

Ankyrin-associated polypeptides dissociated very slowly from the ankyrin–IgG complex, with less than 10% loss during a 90-min incubation at 37 °C (not shown). Conditions have not yet been developed to separate ankyrin from these proteins without using denaturing conditions. It was therefore not feasible to carry out reassociation experiments with isolated components of the complex.

Gel filtration of solubilised membranes on an Ultrogel AcA22 column separated ankyrin-linked band 3 from the major pool of band 3 in mild conditions (Fig. 4) and confirms the existence of an oligomer containing ankyrin, and bands 3 and 4.2 as its principal components. Immunoadsorption of the fractions with anti-ankyrin IgG precipitated a single broad peak which migrated with an effective Stokes' radius of about 90 Å, and preceded the major peaks of radioactivity (Fig. 3). Ankyrin chromatographed coincidentally with immunoreactive material, and was associated with bands 3 and 4.2. The relative proportions of ankyrin, band 3 and band 4.2 were about the same in the peak fractions as in the immunoprecipitates, and nearly all the radioactivity was immunoreactive. These fractions re-chromatograph at about the same position (not shown). The major peak of band 3 migrated with band 4.2 with a Stokes' radius of about 58 Å, and was not adsorbed by anti-ankyrin IgG (Fig. 3). Glycophorin labelled with ^{32}P or tritium migrated more slowly than band 3. These results agree with the previous conclusion that bands 3 and 4.2 are associated in detergent extracts, whereas band 3 and glycophorin are dissociated in these conditions[30]. Approximately 80% of band 3 migrated separately from ankyrin, in agreement with the amount of band 3 immunoadsorbed in whole extracts (Fig. 1).

Immunoadsorbed band 3 was present in a 1:1 molar ratio with ankyrin (that is, bands 2.1, 2.2, 2.3) (Fig. 1). (The stoichiometry of band 3 and ankyrin was determined by integration of the area under the respective peaks on autoradiograms, assuming average MWs of 95,000 for band 3 and 200,000 for ankyrin, and that the specific activity of the iodinated polypeptides was the same. This latter assumption is supported by fact that band 3 and ankyrin are labelled in the same relative proportions by Coomassie blue staining as by iodination (Fig. 1).) The major band 3 protein exists as a dimer in erythrocyte ghosts and in Triton X-100-solubilised extracts[30–33]. Band 3 (B3) and ankyrin (A) could thus be arranged as $((B3)_2\text{-}(A)_2)_N$ if the band 3 association remained intact during isolation, or as $((B3)_2\text{-}A)_N$ if the band 3 dimer dissociated in these conditions. Ankyrin and band 3 co-migrated on gel filtration in about a 1:1 molar ratio in mild conditions in which band 3 probably exists as a dimer[30]. It is therefore likely that the ankyrin-linked band 3 oligomer is arranged with 2 mol each of band 3 and ankyrin. This conclusion is supported by the finding that band 2.1 is cross-linked in a dimeric form[31]. In some gel filtration experiments the ratio of band 3 to ankyrin was greater than that of Fig. 3. Thus, additional associations may occur between the ankyrin–band 3–4.2 oligomer and other band 3 molecules, although experimental conditions for stabilising these complexes have not yet been developed.

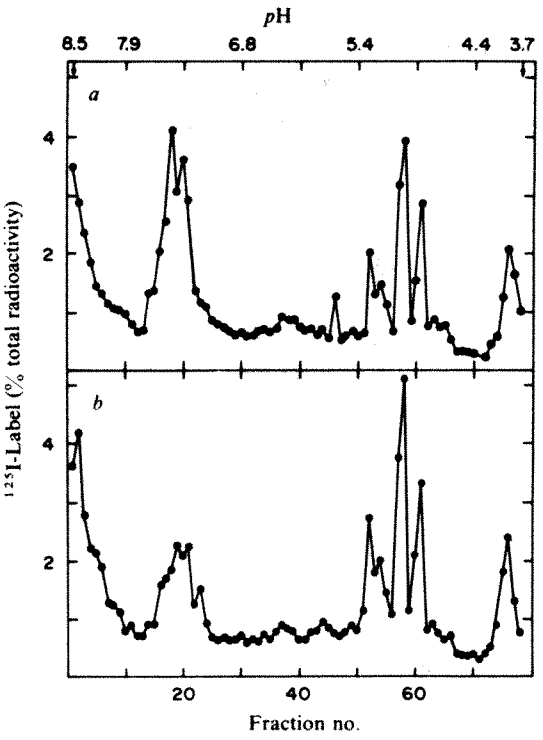

Fig. 4 Isoelectric focusing in polyacrylamide of cyanogen bromide fragments of [^{125}I]-Bolton Hunter-labelled ankyrin-linked band 3 (*a*), and free band 3 (*b*). Ankyrin-linked band 3, isolated by immunoadsorption of solubilised ^{125}I-labelled vesicles (Fig. 1), and free band 3 isolated by gel filtration (Fig. 3) were purified by SDS electrophoresis (Fig. 1). The bands (2×10^5 c.p.m.) were stained with Coomassie blue, cut out and incubated (5 h, 50 °C) in 1 ml of 70% (v/v) formic acid with 40 mg cyanogen bromide. The solutions were separated from polyacrylamide, dried and incubated with 1 M NH_4OH to convert homoserine lactone to the free acid. The samples were reconstituted with 50 μl 9 M urea, 20 mM dithiothreitol, 2% (w/v) ampholines, *p*H 3.5–10 (LKB), and 20 μg ml^{-1} bromphenol blue and analysed by isoelectric focusing (12 h, 1 W) on a 12.5% 1.5-mm polyacrylamide slab gel containing 9 M urea, 1.3% *p*H 3.5–10, 1% *p*H 5–8, 1.3% *p*H 4–6 ampholines and 0.2% Triton X-100. The gels were sliced and radioactivity determined. The data are expressed as the per cent of the total radioactivity recovered from the gel.

Ankyrin-linked band 3 is indistinguishable from free band 3

It was important to determine whether ankyrin-associated band 3 has similar properties to those attributed to the major band 3 protein. Ankyrin-linked band 3 and the total band 3 were both phosphorylated following incubation of intact cells with $^{32}P_i$ (Fig. 2). External cleavage of erythrocytes with α-chymotrpysin reduced both classes of band 3 to a characteristic 55,000-MW membrane-bound fragment[23,34,35] which retained ^{32}P-label (Fig. 2). The ^{32}P-label was cleaved entirely from these fragments by a second digestion of inverted vesicles (not shown), indicating that it is localised on the cytoplasmic surface of the membrane. Thus, ankyrin-linked band 3 spans the membrane, and exhibits a significant similarity to the major band 3 protein.

A more detailed comparison of these polypeptides was provided by isoelectric focusing of cyanogen bromide fragments of SDS-PAGE-purified ankyrin-linked band 3 from immunoprecipitates and free band 3 from gel filtration (Fig. 4). The patterns are nearly identical for the two proteins, although relative peak heights differ (Fig. 4). This difference may be explained by the

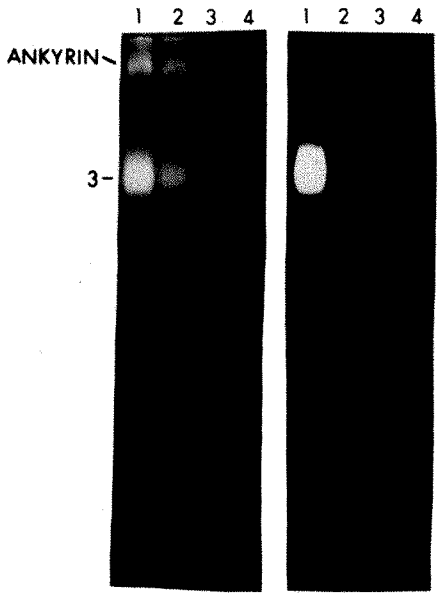

Fig. 5 Binding of purified spectrin to ankyrin-linked band 3 and to free band 3. ^{125}I-Labelled samples from gel filtration of solubilised spectrin-depleted vesicles (Fig. 3) containing ankyrin and band 3–4.2 (left panel, lane 1) or band 3–4.2 free of ankyrin (right panel, lane 1) were incubated (90 min, 4 °C) with 75 μg ml^{-1} purified unlabelled spectrin[17,18] in the absence (lane 2) and presence (lane 3) of 100 μg ml^{-1} unlabelled spectrin-binding fragment of ankyrin[19] in column buffer (Fig. 3). Some of the samples (lane 4) had been acidified to *p*H 2 with HCl and neutralised before addition of spectrin. Spectrin-[^{125}I]-protein complexes were precipitated by addition of monospecific anti-spectrin IgG (affinity purified) and protein A staphylococci, and the pellets were washed with column buffer. The immunoadsorbed proteins were analysed by SDS electrophoresis (Fig. 1) and visualised by autoradiography. The same amount of spectrin was precipitated in the presence or absence of the ankyrin fragment as determined from Coomassie blue staining (not shown).

fact that labelling was carried out with intact vesicles, and bound ankyrin could have altered the reactivity of portions of the band 3 polypeptide. Further evidence that ankyrin-linked band 3 is closely related to free band 3 is that antibodies raised against the 42,000-MW cytoplasmic domain of band 3 (ref. 35) cross-react with both polypeptides (in preparation).

Spectrin binds to ankyrin-linked band 3 but not to free band 3

Incubation of purified spectrin with ^{125}I-labelled ankyrin and band 3–4.2 isolated by gel filtration produced a spectrin–ankyrin–band 3–4.2 complex which was immunoprecipitated by monospecific anti-spectrin IgG (Fig. 5). The complex did not form if these proteins were exposed to acidic *p*H before addition of spectrin (Fig. 5), a treatment which destroys the spectrin-binding capacity of membranes[18]. The association of spectrin with these polypeptides was mediated by ankyrin, as the unlabelled spectrin-binding fragment of ankyrin reduced binding by 90% but had no effect on immunoadsorption of spectrin (Fig. 5). Furthermore, when isolated by gel filtration, band 3–4.2 (lacking ankyrin) did not bind to spectrin (Fig. 5). Other fractions from Fig. 3 also exhibited no binding to spectrin (not shown).

These results indicate that spectrin can reassociate with its membrane attachment site in the presence of Triton X-100. Consequently, it would be expected that the complex of spectrin–ankyrin–band 3–4.2 would be retained by the cytoskeletal assembly which remains after extraction of erythocytes and ghosts with Triton X-100[36,37]. Nearly all of spectrin and 10–15% of band 3 are recovered in Triton X-100-extracted ghosts along with bands 4.1, 4.2 and 7, and erythrocyte actin (Fig. 6). This residual band 3 is tightly adsorbed, and persists at a constant level during repeated washes in detergent (Fig. 6). Ankyrin is poorly visualised due to interference by spectrin, but is detected by radioimmunoassay in the same amounts as in whole ghosts (not shown). Furthermore, ankyrin together with band 3, band 4.2 and band 7 can be extracted without solubilising these Triton residues[38] (Fig. 6). Cytoskeleton-linked band 3 is cleaved to a 55,000-MW fragment by external cleavage of erythrocytes with α-chymotrypsin before detergent extraction (Fig. 6). A second limited digestion of the cytoskeletons with α-chymotrypsin cleaves band 3 and the 55,000-MW fragment (not shown). It can thus be concluded that the cytoskeleton-bound band 3 spans the membrane and is the same polypeptide as the ankyrin-linked band 3.

Discussion

These data indicate that about 15% of band 3 is tightly linked to the erythrocyte cytoskeleton through association with ankyrin, with a stoichiometry of 1 mol band 3 per mol of ankyrin. The ankyrin– band 3 oligomer also contains a 72,000-MW polypeptide (band 4.2) which has been demonstrated to bind to band 3 in solution[30]. Band 3 is present in about 10^6 copies per cell arranged in a dimeric form visualised as intramembrane particles[32]. Ankyrin, which is present in about 10^5 copies per cell, is thus associated with 10^5 band 3 molecules which are presumably also dimers and form from 5×10^4 to 10^5 intramembrane particles, depending on the ankyrin–particle stoichiometry. These ankyrin-linked structures are also the points of attachment of spectrin to the membrane, and may be nucleation sites for assembly of the cytoskeleton. The average nearest neighbour distance between ankyrin–band 3–4.2 oligomers would be 350–500 Å, which is comparable to the dimensions of tetrameric spectrin[39], the form of this protein in erythrocyte ghosts[39,40]. Scanning electron microscopy of erythrocyte ghosts and cytoskeletons reveals a net-like appearance with globular structures 200–1,000 Å apart interconnected by filaments[41]. These dimensions are consistent with the possibility that the interstices of the network contain ankyrin-linked oligomers.

The finding that only a fraction of band-3 proteins are linked to spectrin helps reconcile two conflicting sets of data regarding association of integral proteins with the cytoskeleton in red cell membranes. Spectrin, and possibly actin, are thought to restrict lateral translation of intramembrane particles[15] and to be associated with sialoglycoproteins[16]. Spectrin has been localised in

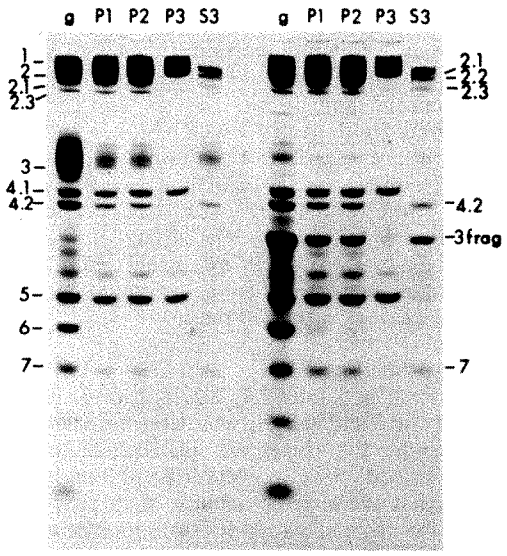

Fig. 6 Retention of band 3 in Triton X-100-extracted cytoskeletons of erythrocyte ghosts. Ghosts were prepared from erythrocytes that were untreated (left) or had been digested externally with α-chymotrypsin (right) as in Fig. 2. Cytoskeletons were prepared by incubating (15 min, 4 °C) the ghosts with 20 vol of 100 mM KCl, 10 mM $NaPO_4$, *p*H 7.5, 1 mM NaEDTA, 10 μg ml^{-1} phenylmethylsulphonyl fluoride, 0.2 mM dithiothreitol and 0.2% (v/v) Triton X-100. Cytoskeletons were pelleted (15 min, 40,000*g*) (P1), washed once in extraction buffer (P2) and incubated (15 min, 0 °C) in extraction buffer plus 1 M KCl. The suspensions were pelleted, the supernatants (S3) removed and dialysed, and the pellets (P3) resuspended in the original volume. The samples were analysed by SDS electrophoresis (Fig. 1) and proteins stained with Coomassie blue.

patterns coincident with intramembrane particles[42]. The lateral mobility of integral membrane proteins is restricted, with a diffusion constant of 5×10^{-12} cm^2 s^{-1} at 22 °C (refs 43, 44), and capping of lectins does not occur in erythrocytes[4]. These experiments have led to the view that intramembrane particles and their component proteins are attached to the cytoskeleton. However, no association could be demonstrated between spectrin and Triton X-100-solubilised band 3 or glycophorin[30]. A direct role for band 3 and the sialoglycoproteins in the attachment of spectrin to the membrane has been ruled out by several experiments[18–20]. The rotational diffusion of band 3 occurs at a rate which indicates that the membrane viscosity should support lateral diffusion at 10^{-9}–10^{-10} cm^2 s^{-1} (ref. 45). Moreover, rotational diffusion of band 3 was unchanged following extraction of spectrin[45]. Further evidence that integral proteins are not all immobilised is the formation of membrane vesicles depleted of spectrin and actin, but containing a full complement of integral proteins[46,47].

The data indicating that band 3 is unrestricted in the membrane are consistent with the present results that only ankyrin-associated band 3 is linked to spectrin. The fact that immobilisation of only a portion of band 3 proteins apparently leads to restriction of all these proteins suggests the involvement of an additional process. It is conceivable that the free proteins are simply entangled in the underlying cytoskeletal meshwork. Another possibility is that the integral proteins associate with each other with low affinity. It is pertinent to this point that intramembrane particles are not dispersed randomly, but rather exist in groups of two to eight. The effect of such aggregation would be to decrease the diffusion constant due to increased size, and to immobilise particles associated with an ankyrin-linked particle.

These studies may have direct relevance to cells other than erythrocytes, as ankyrin has been detected by radioimmunoassay in many tissues and cell types[48]. Future areas of interest include elucidation of the nature of the linkage between band 3 and ankyrin, the role of band 4.2 in this complex, and examination of possible association between ankyrin, band 3 and other membrane proteins such as hormone receptors.

We thank Dr Michael Sheetz for sharing data before publication which demonstrated that cytoskeleton-linked band 3 can be released by high salt extraction.

Note added in proof: Further evidence for association of a portion of the band 3 proteins with the cytoskeleton is provided by the finding that a small amount of band 3 can be chemically cross-linked to band 1 of spectrin in erythrocyte membranes[50].

A precessing ring model for SS433

THE wavelengths of the shifted optical lines in SS433 seem to show a periodic variability at a period of 160 ± 3 d (or a multiple integer thereof)[1,2]. We have suggested that such periodicity could arise if the lines were emitted from a precessing ring of matter orbiting around a massive black hole (BH) of mass M (ref. 3). We also suggested that SS433 may be located inside an old globular cluster[3]. We describe here, in principle, how such precession model may come about and what some of its observational constraints might be.

We suggest that a normal, solar type, star has been captured[4] by a $\sim 10^6\, M_\odot$ BH. Its orbit then circularises at the tidal radius[5], which is located at $R \sim 45\, R_G (R_G \equiv GM/c^2)$, as is indicated by the wavelengths of the shifted lines[3,2]. Note that the tidal radius for this captured star, of average density ρ, is given by[6]

$$R_T \sim 45 \left(\frac{\rho}{1\ \mathrm{g\ cm^{-3}}}\right)^{-1/3} \left(\frac{M}{3\times 10^6\, M_\odot}\right)^{-2/3} R_G$$

and that the lifetime of that orbit against gravitational radiation is[5]

$$(R/\dot{R})_T \equiv \tau \sim 10^6 \left(\frac{M}{3\times 10^6\, M_\odot}\right)^{-2/3} \ \mathrm{yr}$$

(The lifetime may be shorter when appreciable gas dissipation occurs).

We now assume that this star experiences steady Roche-lobe overflow due to either self expansion or steady drift inwards. Once overflow commences, the particle jet through L1 follows an orbit which is almost identical to that of the star, because of the relative smallness of the stellar Roche-lobe radius (this is unlike some 'normal' X-ray or dwarf novae binaries, where the jet goes right into the other lobe). The jet thus forms a cool circular keplerian ring (or torus) around the BH, of small width

$$\sim 0.04\, R \left(\frac{r}{10^{11}\ \mathrm{cm}}\right)\left(\frac{3\times 10^6\, M_\odot}{M}\right)$$

0028-0836/79/330473-02$01.00

where r is the stellar radius. This ring is steadily controlled by the L1 overflow.

We assume the BH to be rotating, not necessarily at extreme Kerr frequencies, because such massive BHs tend to reduce their a/M when 'swallowing' stars[7]. If the star is orbiting in an inclined orbit, a precession of its orbital plane around the rotation axis will occur due to the spin–orbit coupling, at a period given by[8]

$$T_p \sim 48.6\,\mathrm{d}\left(\frac{a}{M}\right)^{-1}\left(\frac{M}{3\times10^6\,M_\odot}\right)\left(\frac{R}{45\,R_G}\right)^3$$

This period will be consistent with the value of 160 ± 3 d for $a/M\sim1/3(M/3\times10^6\,M_\odot)$. (Note that a mass $M>10^7\,M_\odot$ will not be consistent with this model if the period is, indeed, 160 d).

A similar precession motion is also performed by the ring particles, at slightly different frequencies; however, as the ring is always additionally controlled by the L1 overflow, with a time scale of ~100 orbital revolutions ($\gtrsim10$ d), it moves essentially with the stellar precession, having a 'thickness' comparable to its width. This time scale is, essentially, the time it takes for a matter blob leaving L1 to separate from L1 by about an orbital length, and the 'thickness' results from the precession frequency gradient across the ring.

Frictional processes in the ring will bring about a slow drift inwards of 'old' ring material and, eventually, because of dephasing of its precessional motion, its settling down to the outer ring of an equatorial disk[9], which is where all of these out-of-phase inclined inner rings intersect. The disk may have pre-existed around the BH[3]. It provides continuum UV and optical flux to excite the 'new', cold, ring (jet) material into line emission. As the 'old' material drifts inwards, its density first decreases in the diffusion process and then it heats up on approaching the disk. Both these effects should secure the uniqueness of that ring, relative to all material inside it, as an optical line emitter. Note that since the inside material tends more and more to lie in the BH equator[9], the ring is likely to 'see' the inside UV source without much interruption from intervening opacity. The volume of the ring is $\sim10^{37}$ cm^3, requiring a density of $\gtrsim5\times10^{11}$ cm^{-3} (ref. 10) to account for the observed line luminosity. A cool ring of such dimensions and density and with solar type composition will indeed be optically thick to UV radiation but marginally optically thin in the visible when viewed pole-on.

To analyse observational constraints on our model, we write the centre of mass (COM) of the lines[3] as

$$\frac{1}{2}\frac{v^2}{c^2}+\frac{\phi}{c^2}\equiv\frac{3}{2\eta^2}\frac{v^2}{c^2}\simeq0.033 \qquad \text{(ref. 2)}$$

with ϕ the gravitational potential and v the velocity of the emitting region. For ring geometry $\eta^2=1$, while $\eta^2\sim3$ for $v^2\gg\phi$.

Recent data of Abell and Margon[11] suggest that the ring radiation geometry should be such that the ring does not radiate homogeneously but rather radiates predominantly from the regions which lie close to the BH equator, possibly due to the hot outer ring of the disk[15].

This geometry is equivalent to the double-water-hose kinematic geometry of Milgrom[2] and Abell and Margon[11], except that for the ring, $\eta^2=1$ while Abell and Margon take $\eta^2=3$, (that is, they use $v/c=0.27$ while we have $v/c\simeq0.15$). On repeating the Abell and Margon[11] analysis for $\eta^2=1$, we find that

$$(i,\theta)\cong(66°,32°)\text{ or }(32°,66°)$$

where θ is the angle between the plane of the ring and the BH rotation axis, and i is the angle between the line of sight and the BH rotation axis.

The width of the shifted lines emitted from these nodal regions depends on the length of these regions and on the thickness of the ring. Note that since the intrinsic intensity distribution per unit Doppler-shifted frequency along such ring segment maximises, almost always, at one end[3], and since the illumination should maximise at about the middle of the segment, one may sometimes expect double-peaked lines to be observed, depending on the relative heights of these maxima. Furthermore, as the optical depth through which the segment is viewed in the lines increases when the line of sight becomes more parallel to it, one also expects intensity variations with precessional phase.

Finally, we mention briefly a possible origin for the unshifted lines in the spectrum of SS433, which show a variability over time scale of a day[12], self-absorption and widths of $\gtrsim1{,}000$ km s^{-1}. Such variability limits the emission region to $\leq2\times10^{15\text{–}16}$ cm. For a BH of $\sim10^6\,M_\odot$, velocities of a few thousand km s^{-1} are compatible with such distances. If SS433 is accreting clouds, possible in the SNR W50 (ref. 3), moving at $\gtrsim100$ km s^{-1}, or else is accreting interstellar gas[3] moving at $\gtrsim10$ km s^{-1},

$$\left[\left(\frac{n}{1\ \mathrm{cm}^{-3}}\right)\left(\frac{v}{10\ \mathrm{km\ s}^{-1}}\right)^{-3}\sim0.01-1\right],$$

then cooling in the accreted matter will be efficient down to $\sim10^{15\text{–}16}$ cm[13]. In that region, density and temperature may be adequate to emit most of the unshifted emission lines, and its illumination and velocity distribution, modified by angular momentum of infalling matter[13], may cause the line width and shape (see for example ref. 14). Note that the interior part of the accreting matter may become sufficiently hot to radiate at X-ray wavelength, and that its influence on the kinematics and structure of the ring will be small due to the high, supersonic, velocities. It may, however, deposit by electrons up to $\sim3\times10^{36}$ erg s^{-1} in the ring, to add to its excitation.

We thank A. Dekel, J. Katz and Y. Tuchman for discussions. T.P. thanks the NSF for support (through grant PHY77-22489).

On the nature of SS433

THE report of large wavelength variations associated with SS433[1] illustrates the large amount of information to be gleaned from preliminary data when effects large enough to involve the theory of relativity are present. It seems most plausible to interpret the large periodic wavelength variations in the Balmer lines of this object as arising from periodic motion, requiring, as a result of its magnitude, the special relativistic Doppler formula for its interpretation. Here we comment on some recent observations that have made it possible to make quantitative estimates of some aspects of the model.

If the motion may be characterised by a constant speed, then the classical Doppler effect contains information about the radial velocity, while the special relativistic form also involves

0028-0836/79/320474-02$01.00
© Macmillan Journals Ltd 1979

the actual speed. The relativistic expressions for these parameters are

$$\frac{v \sin i}{c} = (z_2 - z_1)/(2 + z_1 + z_2)$$
$$\text{and} \quad \frac{v}{c} = [1 - 4/(2 + z_1 + z_2)^2]^{1/2} \quad (1)$$

where z_1 and z_2 are the minimum and maximum values respectively for the observed redshift relative to the centre of mass. Using the values given for the object in ref. 1, one finds that it may be characterised by a velocity of 80,000 km s^{-1}, inclined 30° to the plane of the sky.

Since the object exhibits both X rays[2] and spectral lines of hydrogen and neutral helium[1], it seems reasonable to suggest that the latter are formed far from the ionising effects of the former. Thus any attempt to achieve the observed velocities by dynamical means incorporating the observed period of 160 d[1] requires a mass in excess of 10^8 solar masses. If the distance of 3.5 kpc (ref. 3) is correct then the presence of such a massive object is incompatible with stellar dynamics in that region of the Galaxy. Thus it is plausible to suggest that some form of hydromagnetic acceleration is responsible for the extremely large velocity. It has also almost become commonplace to suggest accretion by a collapsed object as the source of X rays in other systems exhibiting periodic variations.

These two suggestions strongly imply that a stellar binary system exists, one component being a rather massive star possessing a strong magnetic field (not unlike VV Cephei[4]), and the other a collapsed object, which is indeed the source of the X-ray spectrum. The rapid mass loss from the star would force matter not only through the inner lagrangian point but also through the outer lagrangian points, into the magnetic field. Except for the immediate X-ray shadow cast by the star, this material would be fully ionised by the X-ray source, and thus be frozen to the co-revolving magnetic field of the star. This ionised material would be accelerated outwards until it exceeds the Alfvén velocity or passes the Strömgren radius dictated by the X-ray source. The outward motion could be expected by means of cyclotron radiation to produce the observed non-thermal radio radiation[5]. At the Strömgren radius, the material will radiate and rapidly cool, giving rise to the observed high-velocity cool gas spectrum.

Additional observational data have recently become available which enable us to make quantitative estimates of several aspects of this model. The observed Hα flux of Liebert *et al.*[6], the 3.5 kpc distance, and the reddening of Margon *et al.*[3] imply an emitted energy at Hα of about 3×10^{34} erg s^{-1} or 5×10^{45} Hα photons per s per stream. If β is the number of Hα photons emitted for each outflowing proton, then the implied mass outflow would be 10^{-4} per β solar masses per yr. The divergence of the field would allow the material streaming outwards to spread, so that radiation is produced in a large volume. If the emitting region subtends about 15° as seen from the binary, then the time required for this region to cross the location of maximum Doppler shift would be about 4% of the 160 d period, and would produce the flat tops of about one week duration of the radial velocity curves[1]. The rotationally outflowing material will compress the field in the rotational plane over that of a static dipole geometry, in a manner perhaps similar to that of the Sun or Jupiter. As the distance from the binary system increases, the weakening field will form a spiral, which when combined with the above compression, yields a field decreasing in strength much more slowly than a static dipole field. This phenomenon is well observed in both the Sun and Jupiter, and implies a field strength that varies with distance as $r^{-\alpha}$, with $\alpha \approx 1.3$ (ref. 7). The spiraling of the magnetic field lines implies that the mass motion at time of radiation will have both tangential and radial components. If we take the magnetic and kinetic energies to be equal in the radiating volume, and equating the radial and tangential velocity components, then assuming co-rotation, the distance to the emitting regions is fixed. In addition, the previously calculated mass flux will specify the density, and hence the magnetic field strength, in the emitting region. If we extrapolate the field to the stellar surface using the above power law dependence, we may place a lower limit on the mass of the star such that it is stable against magnetic distortion[4]. The expression that relates these parameters is

$$\frac{M_*}{M_\odot} \geq \frac{10^{-8} v^{\alpha+1} P^\alpha \sin^\alpha \xi}{R_\odot^\alpha (2\pi)^{\alpha-1/2}} \left(\frac{R_*}{R_\odot}\right)^{2-\alpha} \rho^{1/2} \quad (2)$$

where ξ is the radial angle of the recombining gas, which we have taken to be 45°. With the previously determined values of α, period P and velocity v, this becomes

$$\frac{M_*}{M_\odot} \geq 1.4 \times 10^9 (R_*/R_\odot)^{0.7} \rho^{1/2} \quad \text{cgs} \quad (3)$$

The geometrical arguments previously mentioned and the outflowing particle flux yield a density in the beam of

$$\rho = 4\pi N m_H (\beta v^3 P^2 \theta^2 \cos \xi \sin^2 \xi)^{-1} \approx 1.6 \times 10^{-19}/\beta \text{ g cm}^{-3} \quad (4)$$

where N is the number of Hα photons emitted per s and θ is the half-angle subtended by the emitting regions as seen from the binary system. We may take the keplerian separation implied by the large mass indicated in equation (3), and the period P, to suggest an upper limit to the stellar radius of 2 AU. Equation (3) implies a lower limit to the mass of the primary of 40 $M_\odot/\beta^{1/2}$.

The absence of forbidden lines in the spectrum of SS433 and the recombination time for the hydrogen spectrum require a high-density medium for the emitting region. In order to keep the kinetic energy loss through the beam within reasonable bounds, one would expect the beam density to be low. These two requirements suggest a high speed particle beam interacting with a high density medium at the boundary of the Strömgren sphere. Although the details of such an interaction are complicated, mechanisms such as charge exchange imply that a value of β very much larger than that obtained from classical recombination theory would result. A large value of β implies that typical stellar masses would be gravitationally stable against the required stellar magnetic field. The evidence that the object contains a massive blue star[8] indicates that the field, although large, can be well below the disruption strength. Also a large value of β reduces the required mass loss rate to values typical for massive stars.

Thus we see that many aspects of this object are consistent with a model containing a massive blue star of the order of 50 solar masses in orbit with a collapsed object, separated by about 3 AU. The strong magnetic field of this blue star declines slowly with distance to a value of about 1G at 1,000 AU, where the outflowing matter interacts with the surrounding medium. Note that this distance, which is largely set by the geometry of the model, is consistent with the Strömgren radius expected for the X-ray source[2] and densities we have used.

Recently Abell and Margon[9] have shown that the shape of the observed segment of the radial velocity curve implies that the expanding streams may be inclined to the orbital plane at the location of emission. If confirmed, this interpretation would imply that the stellar field be inclined to the orbital plane, introducing only minor modifications to our model.

Cool gaseous nebulae

THE electron temperatures of diffuse gaseous nebulae have long been thought to be close to 10^4 K. Much lower temperatures were derived from some of the early radio continuum and recombination line work, but these were generally considered to be wrong for a variety of reasons (cf. the review by Seaton[1]). However, most of these considerations applied only to the easily measurable bright nebulae like Orion, and these are expected to be at high temperatures because of their high densities and the effects of collisional de-excitation on cooling agents such as oxygen and neon ions[2]. While there is little doubt that the bright nebulae do indeed have temperatures of ~8,000–9,000 K (refs 3–5), there are strong indications that some nebulae of lower densities have much lower temperatures, ≲4,000–5,000 K (ref. 5). We have made radio recombination line observations of several low-density nebulae, in order to determine electron temperatures in the absence of such effects as collisional de-excitation, stimulated emission, and pressure broadening. Several of these nebulae have been found to have temperatures below 5,000 K, and for two of them which are discussed here (RCW94 and G339.1–0.2) absolute upper limits of ~4,700 K are imposed by the line widths alone.

The observations were made at 5 GHz with the Parkes 64-m radio telescope in March and April 1979. The system temperature was about 50 K, and the half-power beamwidth 4.4 ± 0.1 arc min. The temperature scale was based on observations of Hydra A, assumed to have a flux density of 13.1 Jy; the ratio of point source flux density to main beam brightness temperature was 1.43. The digital correlation spectrometer provided two simultaneous 512-channel spectra of a 10-MHz band containing the H 109α, H 137β, and He 109α lines; the spectral resolution was 2.3 km s^{-1} after Hanning smoothing. The total power observing mode was used; after each on-source integration, lasting 20 min, a reference integration of the same duration was made over the same range of hour angle. Special care was taken to assure compatibility of the continuum and line observations; the continuum measurements were interspersed with the line measurements of a given source, and were made with long scans through the peak of the source in order to separate the source from the galactic background accurately. The final spectra of the two sources RCW94 and G339.1−0.2 are shown in Fig. 1, compared with a spectrum of the Orion Nebula; measured and derived parameters are given in Table 1.

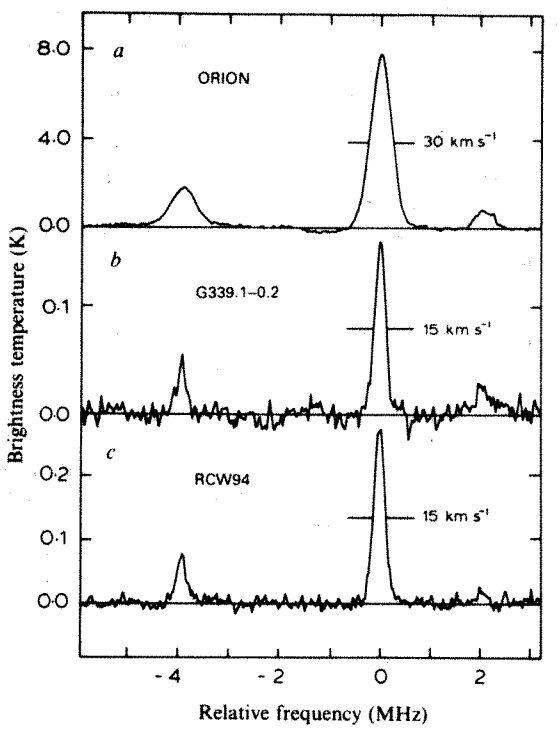

Fig. 1 5-GHz recombination line spectra of the Orion Nebula (*a*), G339.1–0.2 (*b*) and RCW94 (*c*). Hanning smoothing has been applied. A quadratic baseline was removed from the spectrum of the Orion Nebula and linear baselines from those of G339.1 − 0.2 and RCW94. The frequency scale is relative to the H 109α line; the H 137β and He 109α lines appear at −3.890 and +2.041 MHz respectively.

Table 1 Observed and derived parameters

	RCW94	G339.1 − 0.2
α (1950)	15 h 38 min 13 s	16 h 40 min 48 s
δ (1950)	−54°06.7′	−45°58.5′
T_C(K)	1.69 ± 0.09	0.85 ± 0.05
H 109α:		
ΔT_L	0.273 ± 0.005	0.160 ± 0.005
ΔV_L (km s^{-1})	14.9 ± 0.2	14.9 ± 0.3
V_L (km s^{-1})	−43.1 ± 0.2	−119.7 ± 0.2
I(H 137β)/I(H 109α)	0.27 ± 0.02	0.28 ± 0.02
I(He 109α)/I(H 109α)	0.06 ± 0.02	0.10 ± 0.02
T_D(K)	4,730 ± 130	4,730 ± 190
T_e^*(K)	4,660 ± 280	3,960 ± 280
T_e(K)	4,490 ± 280	3,800 ± 280

Quoted errors are 1 s.d. and allow for baseline uncertainties. Continuum (T_C) and peak line (ΔT_L) temperatures are in units of brightness temperature averaged over the main beam. The linewidth (ΔV_L) is the FWHM value, and the line velocity (V_L) is with respect to the local standard of rest. The integrated line intensities (I) were obtained by integrating under the observed line profiles. The Doppler temperature (T_D) allows for the instrumental resolution of 2.3 km s^{-1}. T_e^* and T_e are electron temperatures computed from the line-to-continuum ratio; LTE was assumed in determining T_e^*, and T_e takes into account all non-LTE effects assuming a local electron density of 100 cm^{-3}.

The most striking features of these lines are their widths, both 14.9 km s^{-1}. This is extremely small compared with the widths of recombination lines from other gaseous nebulae; the average of 128 lines observed in one survey[6] was 34.5 km s^{-1}, and the Orion Nebula with a linewidth of 30 km s^{-1} is typical of bright nebulae. These narrow lines almost certainly originate within the nebulae themselves, and not from cold partially ionised regions which may surround the nebulae; supporting evidence includes the absence of any significant carbon recombination line emission, approximately normal helium-to-hydrogen line intensity ratios, and β/α ratios close to the local thermodynamic equilibrium (LTE) value of 0.276. In addition the observed H 109α profiles are well represented by single gaussians; if some fraction of the line emission were supposed to originate outside the nebulae, the central velocities of the two line components would have to agree within ~0.5 km s^{-1}, and the widths and intensities would have to be interrelated to an improbable degree to satisfy the tight condition that the overall line shape is nearly gaussian. The linewidths thus imply an absolute upper limit of 4,730 K (T_D in Table 1) for the electron temperatures of the nebulae. If there are any turbulent mass motions, the electron temperatures must be smaller still.

The electron temperatures determined from the line-to-continuum ratios are consistent with these upper limits. Assuming LTE, they are 4,660 and 3,960 K for RCW94 and G339.1 − 0.2 respectively. Corrections for non-LTE effects reduce these temperatures still further, to 4,490 and 3,800 K respectively assuming a local electron density of 100 cm^{-3} (the corresponding β/α ratio is 0.29 in both cases); these corrections include stimulated emission due to the continuum from the nebulae, the galactic background, and the 2.7 K microwave background (about 5% of the total line emission). The r.m.s. electron density is ~20–30 cm^{-3} for both nebulae, so the adopted local value corresponds to filling factors of ~0.05–0.10, typical values; use of the r.m.s. densities gives the lowest possible values for the electron temperatures, 4,130 and 3,530 K for RCW94 and

0028–0836/79/330476–02$01.00

G339.1−0.2 respectively, but the temperatures obtained using a density of 100 cm^{-3} are probably more realistic. The corresponding r.m.s. turbulent velocities are small, ~3–5 km s^{-1}, as might be expected for well evolved, low-density nebulae such as these.

The low electron temperatures probably require relatively high metal abundances[7,8]. The normal helium-to-hydrogen line intensity ratios suggest that the nebulae are fully ionised. The excitation parameters (90 and 60 pc cm^{-2} for RCW94 and G339.1−0.2 respectively) correspond to early O-stars; the exciting star of RCW94 has been identified as LS3386 (ref. 9), and recent near-IR measurements of it (to be published) are consistent with an O5 star at the distance of the nebula (2.7 kpc), with $A_V \sim 5$. And recent work indicates that dust which may be present in the nebulae could not produce the necessary cooling[10]. The most likely explanation for the low temperatures is therefore a high metal abundance; indeed, recent radio and optical observations of another low-temperature nebula, G339.2−0.4, reveal metal abundances higher than the solar values by a factor of 4–5 (ref. 11).

We thank Lynette M. Newton and Dominic M. Zarro for assistance with the observations and data reduction. P.A.S. thanks the staff of the CSIRO Division of Radiophysics for their hospitality.

Note added in proof: New optical observations of RCW94 (in preparation) reveal metal abundances higher than the solar values by a factor of 6–7.

Measurements of the trigonometric parallax of pulsars

THE distances of pulsars from the Earth have been determined using the dispersion measure and an assumed constant value of the mean electron density through the Galaxy of about 0.03 cm^{-3}. Independent distance estimates are available for a number of distant pulsars from the measurement of the H I absorption in the pulsar radiation and these results are in general accord with the dispersion measure estimates over large distances through the Galaxy. There is some indirect evidence[1,2] that the mean electron density in the solar neighbourhood is typical of the rest of the Galaxy but all estimates of pulsar distances within 1 kpc of the Sun rely on this assumption. We report here measurements of trigonometric parallax of pulsars and from the distance estimates we obtain a value for the mean electron density within about 500 pc of the Sun.

The observations formed part of the programme at Jodrell Bank for the measurement of the proper motions of pulsars[3]. Observations were made at 408 MHz using a radio-link interferometer between the 76-m MkIA telescope at Jodrell Bank and a 25-m telescope at Defford, a baseline of 127 km length. The technique involved a search for apparent motion between the pulsar and one or two nearby small diameter radio sources, assumed to be extragalactic and much more distant than the pulsar. Observations were made over a period of between 2 and 4 yr, each pulsar being observed once or twice a year.

Table 1 Parallax determinations with r.m.s. error $<10^{-2}$ arc s

Pulsar	Parallax (p) (10^{-3} arc s)	Dispersion measure (D) (pc cm^{-3})	Electron density (n_e) (cm^{-3})
0329+54	1.3±1.7	26.8	0.035±0.046
0809+74	1.8±7.1	5.8	0.010±0.041
0950+08	8.3±8.8	3.0	0.025±0.026
1237+25	−6.2±5.2	9.3	−0.058±0.048
1818−04	3.1±6.1	84.4	0.262±0.515
1929+10	21.5±8.0	3.2	0.069±0.026
2016+28	0.9±3.6	14.2	0.013±0.051
2020+28	−1.3±4.6	24.6	−0.032±0.113
2021+51	1.8±4.9	22.6	0.041±0.111

A least squares fitting process was used to determine linear proper motions in right ascension and declination and the parallax. For many of the pulsars most of the observations were made when the Earth was in approximately the same part of its orbit around the Sun so that the parallactic motions were small and consequently the errors in the measured parallaxes large. However, for nine pulsars out of the 26 studied, data were collected sufficiently often to allow determinations of parallax with r.m.s. errors of <0.01 arc s and these are listed in Table 1. The measured proper motions are not included and the complete results for all 26 sources will be published elsewhere. The major errors in the parallax determinations, apart from the random errors caused by poor signal-to-noise ratios and limited sampling through the year, are due to secular variations in the properties of the ionosphere. Systematic errors are to be expected because of the solar cycle and annual ionospheric variations above the observatories. There are not sufficient ionospheric data to make accurate corrections to the observations but a computer analysis using plausible data indicates that these errors amount at most to a few milliarcseconds per year in proper motion and a few milliarcseconds in parallax. This is confirmed by the small parallaxes measured on some of the pulsars which have large dispersion measures and are therefore expected to be very distant. The dispersion measures are shown in Table 1. The errors in these values are all <1% (ref. 4).

Taken individually, only one pulsar, PSR1929+10, shows a significant parallax of 21.5±8.0 marc s. This pulsar has the second smallest dispersion measure of all known pulsars and the parallax places the pulsar at a distance of about 50 pc from the Sun. The mean electron density (n_e) along the line of sight to the pulsar can be obtained from the product of the parallax (p) and the dispersion measure (D). That is

$$n_e = p.D$$

In this case, $n_e = 0.069 \pm 0.026$ cm^{-3}

This is somewhat larger than the mean electron densities measured along the lines of sight to pulsars over large distances through the Galaxy determined from observations of H I absorption. However, this pulsar lies at a low galactic latitude ($b = -4°$) and the line of sight to the pulsar is always within the disk of the Galaxy where the mean electron density is probably enhanced somewhat by material and ionisation associated with the population I stars and H I and H II regions. For pulsars, the galactic height distribution is several times wider than this enhancement, so that most of the lines of sight lie within this layer for only a small fraction of their lengths.

The errors in the parallax determinations for the other pulsars in Table 1 are too large to allow meaningful distances to be estimated. However, because the derived value of n_e is proportional to parallax, it is possible to obtain an unbiassed estimate of the mean electron density for each pulsar and this is shown in

0028-0836/79/320477—02$01.00
© Macmillan Journals Ltd 1979

Table 1. Combining these results we can obtain a weighted mean of 0.029 ± 0.014 cm^{-3}.

There is no strong evidence to suggest any inhomogeneity in the electron distribution, as the individual estimates of the electron density are all substantially in accord with the mean value of about 0.03 cm^{-3} when their errors are taken into consideration.

This value for the mean electron density is derived essentially from those pulsars within about 500 pc of the Sun (that is, dispersion measures <15 pc cm^{-3}) since the estimates of n_e for the more distant objects all have large errors and therefore carry little weight in the formation of the mean. This value of the mean electron density is consistent with estimates over much larger distances in the Galaxy and indicates that the Sun does not lie in a region which is particularly rich or poor in interstellar plasma. The estimates of the local space density of pulsars made by Taylor and Manchester[5] and by Davies, Lyne and Seiradakis[2] were based on assumed mean electron densities of 0.03 and 0.025 cm^{-3} respectively. As the most numerous pulsars in the Galaxy have a very low luminosity, we observe them only within a few hundred parsecs of the Sun. To estimate the local space density of pulsars reliably, it is important to have a good estimate of the local mean electron density near the Sun, or better still a direct measure of distance. It seems therefore that their estimates of the pulsar space density will not be seriously in error due to this assumption and that the rather high pulsar birth rates of between 1 every 4 and 1 every 15 yr required to sustain the derived galactic pulsar population are accordingly still justified. More precise measurements are in progress and will help to determine whether supernovae occur often enough to be the sole birth places of pulsars.

On the Pioneer 11 observation of the ring of Jupiter

SHORTLY before closest approach to Jupiter, the imaging experiment on board Voyager 1 detected a ring of particulate matter around the planet as the spacecraft crossed the equatorial plane of Jupiter. The radial position of the ring is at approximately $1.7R_J$ (jovian radii), the total ring thickness is reported to be ≤ 30 km and the radial extent $\leq 10^4$ km (refs 1, 2). Although this discovery was rather unexpected, the possible existence of a dust belt within the orbit of the innermost satellite, Amalthea, actually had been suspected as a result of the Pioneer 11 measurement of the jovian trapped radiation belt[3,4]. In this note we briefly outline this interesting observation and evaluate some of the basic properties of this newly discovered ring.

During the Pioneer 11 flyby of Jupiter in December 1974, the minimum distance of the spacecraft to the centre of the planet was as small as $1.6R_J$ and hence the intensity variations of the trapped radiation belt charged particles between the outer magnetosphere and the region around $1.6R_J$ were sampled by energetic particle detectors. As in the earlier Pioneer 10 encounter, absorption structures near the orbits of Ganymede ($L = 15.0$), Europa ($L = 9.4$) and Io ($L = 5.9$) were found in the particle fluxes in certain energy channels[3,5-7]. Sometimes the intensity dropped by a factor of 10 in the vicinity of the satellite sweeping corridors. Because of its closer encounter distance, Pioneer 11 enabled a survey to be made of the jovian radiation belt near Amalthea. As well as two absorption features apparently related to Amalthea there are two minima at $L \approx 1.6$ and 1.7 not accounted for by any known satellite[3]. On one hand, such minima may be simply caused by the anamolous precipitation of the mirroring charged particles into the planetary upper atmosphere at this radial distance as a result of the large quadrupole moment of the jovian magnetic field[4,8]. On the other hand, the absorption effect of a small satellite or a ring of dust particles can also produce just such structure in the intensity variations of the charged particles[3,4]. It has been noted, in any case, that even with the anomalous precipitation effect operating in reducing the particle fluxes near the minima in question some particulate matter may still exist and help to sweep up the charged particles in this region[9]. In the light of the Voyager 1 discovery, it seems appropriate to reconsider the Pioneer 11 data in terms of the dust belt interpretation. Because the distances of closest approach to Jupiter for both Voyager spacecraft are more than $4.9R_J$, no information can be obtained for the trapped radiation belt in the vicinity of the ring. This certainly makes the measurements of Pioneer 11 even more interesting. In this letter, we make some estimates (in a manner essentially similar to the treatment discussed by Van Allen[10] for the saturnian rings) of the optical thickness of the ring, number density, as well as the average size of the ring particles. Only proton ($E \geq 80$ MeV) data from the UCSD Trapped Radiation Detector instrument described by Fillius[3] will be used in the present discussion. This calculation, together with the Voyager 1 imaging result, should provide preliminary information on the new ring of Jupiter.

The satellite absorption effect is determined by two basic factors[11-13]: (1) the effective absorption cross-section of the satellite, and (2) the time scale for the charged particles to diffuse across the sweeping corridor of the satellite. Furthermore, the absorption process will be affected by the drift frequency and pitch angle of the particle motion in the dipole field of the planet. If, for a certain kinetic energy, the drift frequency is comparable to the frequency of the relative motion between the satellite and the co-rotating magnetosphere and the two motions are in opposite directions, the resulting 'resonance' would tend to suppress the satellite absorption effect. At the same time, because of the 10° tilt of the magnetic dipole moment with respect to the rotation axis of the planet, mirroring charged particles with equatorial pitch angle larger than 70° would be able to diffuse past the satellite more easily without being absorbed[11]. In the case of absorption of charged particles by a ring of particulate matter, the pitch angle effect might still be important in determining the degree of absorption; but the drift frequency should not influence the particle absorption since the ring particles are presumably distributed uniformly along the whole orbit. The only energy-dependent factor then would be the stopping range of the charged particles, that is the integrated mass intercepted by the charged particles as they diffuse across the ring plane. For 100-MeV protons, the stopping range is typically a few grammes for matter of various composition (ice, aluminium and so on). Hence, if most of the ring particles have sizes of >1 cm, just one pass would be enough to absorb the impacting proton; and the survival probability of the energetic protons as they diffuse inward past the ring can be written as

$$P = \exp(-2N_b\tau_\perp) \quad (1)$$

where N_b is the total number of bounces executed by the mirroring protons and $\tau_\perp$ is the optical thickness in the direction perpendicular to the ring plane. The value of $\tau_\perp$ is related to the number density and average diameter (d) of the ring particles, and the thickness of the ring place ($l_\perp$) by the following expression,

$$\tau_\perp = \pi n d^2 l_\perp / 4 \quad (2)$$

The value of N_b can be approximated by taking the ratio of the pertinent diffusion time scale t_d to the bounce period t_b of the

0028-0836/79/320478—02$01.00

© Macmillan Journals Ltd 1979

100-MeV protons. In the Pioneer measurements, the radial diffusion coefficient (D) for 100-MeV proton is estimated to be $\approx 10^{-6}\ s^{-1}$ at the orbit of Io ($L = 5.9$) and $10^{-8}\ s^{-1}$ at the orbit of Amalthea ($L = 2.6$) (see ref. 12). If D is proportional to L^3 or L^4 the corresponding value at $L \approx 1.7$ is $\approx 7 \times 10^{-9}\ s^{-1}$. Now, according to the preliminary report[1,2], the total radial extent of the ring is $\geq 9 \times 10^3$ km ($\Delta L \geq 0.1$). At the same time, an upper limit for ΔL of about 0.16 can be set from the Pioneer data[3]. The diffusion time scale can then be approximated as[14]:

$$t_d = \Delta L^2 / 4D \tag{3}$$

with $\Delta L \approx 0.1$.

Therefore $t_d \approx 3.6 \times 10^5$ s. The bounce period of mirroring charged particles is given by[15]

$$t_b \approx 5.2 r_0 / V \tag{4}$$

where r_0 is the equatorial radial position of the mirroring charged particle and V its velocity. For $r_0 = 1.7 R_J$ and $V = 1.2 \times 10^{10}\ cm\ s^{-1}$ we have $t_b \approx 5.2$ s; and hence $N_b \approx 7 \times 10^4$. Judging from the depth of the minima in the proton intensity as measured by the UCSD experiment we can put $P = 0.1$ (that is, the flux is reduced by a factor of 10 across the absorption structure). From this we can immediately obtain $N_b \tau_\perp \approx 2.3$ and therefore $\tau_\perp = 6.2 \times 10^{-6}$ for the absorbing particles. Such a small optical thickness may be compared with $\tau_\perp \approx 1$ for the B ring of Saturn[16] and a value between 10^{-7} and 10^{-2} for the D' ring suspected to exist beyond the outer edge of the A ring[17,18]. [The result that the $\tau_\perp$ value of the ring of Jupiter should be a factor of 6×10^{-6} smaller than that of the saturnian B ring is in good agreement with the most recent IR detection of Jupiter's ring[19]. In this observation it is concluded that the number of particles in Jupiter's ring should be of the order of 10^5 less than that in Saturn's if both ring systems have similar kinds of particles and the viewing geometries are about the same.]

If the ring plane thickness $l_\perp$ is known we can derive the product nd^2 using equation (2). No exact value of $l_\perp$ is yet known—only that it is less than 30 km (refs 1, 2). Considering a thickness of ~1 km estimated for the saturnian rings[20] it may be reasonable to adopt $l_\perp \approx 1$ km for the ring of Jupiter as a working number. The actual thickness is not likely to be larger or smaller by a factor of 10. Substitution of this value into equation (2) gives $nd^2 \approx 8 \times 10^{-11}\ cm^{-1}$; that is

$$n \approx 8 \times 10^{-11} / d^2\ cm^3 \tag{5}$$

With the total volume of the ring given as $U = 2\pi r_0 \Delta r l_\perp$ (thus $U \approx 6 \times 10^{24}\ cm^3$ if $r_0 = 1.7 R_J$, $\Delta r = 0.1 R_J$ and $l_\perp = 1$ km) and the density of the ring particles is 2 g cm^{-3}, the total mass of the ring can be expressed as

$$M \approx 5 \times 10^{14} d \text{ grammes} \tag{6}$$

Thus $n \approx 8 \times 10^{-11}\ cm^{-3}$ and $M \approx 5 \times 10^{14}$ g if $d \approx 1$ cm, and $n \approx 8 \times 10^{-21}\ cm^{-3}$ and $M \approx 5 \times 10^{19}$ g if $d \approx 1$ km.

From simple geometrical considerations we find the maximum optical path ($l_\parallel$) along the ring plane as it is observed edge-on to be about $1.1 R_J$, therefore the corresponding optical thickness ($\tau_\parallel$) can be approximated as $\tau_\perp \times (l_\parallel / l_\perp)$, and this gives $\tau_\parallel \approx 0.5$. If the ring particles have a certain size distribution, the bodies with diameter much less than 1 cm may contribute significantly to a total light reflecting area ($A \approx 6 \times 10^{14}\ cm^2$ if $\tau_\perp \approx 6 \times 10^{-6}$) even though their absorption power is rather limited (since most of the mass is likely to be concentrated in the large particles). In this manner, the effective optical thickness may be increased by one or two orders of magnitude—but probably not by a factor much larger—considering the absence of the ring from ground-based observations in the past. If we argue that the ring particles are as old as the Solar System, their size must be large enough to resist orbit decay caused by the Poynting–Robertson effect. Following the similar treatment for the saturnian ring particles[21], the minimum diameter can be estimated to be ≈1 m, at least, for particles carrying most of the mass. A determination of the size distribution could possibly be achieved by analysing the absorption effect on electrons and protons of different energies (since they have different stopping ranges). Before this is attempted, little can be said.

In this connection, we would like to mention that detailed examination of the Pioneer 11 data with a small time resolution may also provide vital information on the radial structure of the ring. For example, the radial distance of the 2:1 two-body resonance with Amalthea is $1.61 R_J$. It would be interesting to see if there is energetic particle signature along the magnetic flux tube in this vicinity indicating the existence of a gap reminiscent of the Cassini's division in the saturnin rings. Or, the orbital resonance may actually define the mass concentration of the ring as previously suggested for the narrow rings of Uranus (but for a different type of orbital resonances) (see refs 22–24). The Pioneer 11 energetic charged particle data might then provide information on the dynamical models of ring formation as well.

Thus, based on the Pioneer 11 UCSD proton ($E \geq 80$ MeV) measurement of the absorption structures in the vicinity of the ring of Jupiter, the optical thickness of the absorbing ring particles in the direction perpendicular to the ring plane is estimated to be about 6×10^{-6}, and the corresponding value as the ring is seen edge-on is approximately 0.5. If the ring is as old as the Solar System, most of the mass should be concentrated in particles with diameter larger than 1 m and the total mass of the ring would be larger than 5×10^{16} g. Comparison with the Voyager imaging data may narrow down the uncertainty. But only further analysis of the energetic charged particle data can give us more insight about the size distribution and radial structure of the ring.

I thank Dr Walker Fillius for very useful discussions since his finding of the 'anomalous' absorption minima inside the orbit of Amalthea. I also thank Professor Ian Axford for a discussion on the L-dependence of the radial diffusion coefficient.

Compositional differences between Arctic aerosol and snow

UNIQUE information on trace elements in polar atmospheres is available through records of deposition in snow and ice. Proper interpretation of these data requires a knowledge of the nontrivial chemical relationship between the deposition and its parent aerosol. Because several complex processes determine the trace-element content of precipitation, polar ice and snow cannot be considered *a priori* to have the same composition as polar aerosol[1]. In most of the current literature, such an assumption is usually made. Within the past year or so, the first tests of the long-term relationship between aerosol and deposition have been (inadvertently) produced for the Antarctic and

Table 1 Elemental concentrations and crustal enrichment factors in Barrow aerosol and snow

the Arctic. The results are different for each region, and illustrate the great caution that must be exercised in this entire field. At the South Pole, snow from 1973–74[2] compares very well with aerosol from 1974–75[3]—both media give the same impression of the environment[2,4]. In the Arctic, on the other hand, opposite conclusions about the atmosphere have been drawn from snow and aerosol, and this problem is discussed here.

Weiss *et al.*[5] have used crustal enrichment factors of trace elements in recent Barrow, Alaska, snow and pre-1900 Greenland ice to conclude that (1) the 'lithospheric' elements Al, V, and Mn are not enriched at Barrow and Milcent (Greenland), and hence are derived from a (natural) 'windborne lithospheric component'; (2) the enrichments of Na, Zn and Cd are similar at Barrow, Milcent, and other Greenland sites (which implies that these elements are natural in origin at Barrow); (3) other enriched elements such as S, Se, Hg, Cd, As and Sb are naturally enriched in pre-1900 Greenland deposits. The overall impression given by Weiss *et al.*[5] is of the natural character of polar deposition in both Greenland before 1900 and Barrow today. Weiss *et al.* refer interchangeably to 'atmosphere' and 'aerosol' 'snow', 'ice', and 'deposit', implying that this natural character also holds for the polar atmosphere.

In contrast, we have recently concluded from chemical analysis of two years' samples of the Barrow aerosol that it is strongly pollution-derived, particularly during winter, to the extent that abundances of even 'lithospheric' elements can be affected[6]. This deduction is based on actual V/Al and Mn/Al ratios, which are more characteristic of mid-latitude pollution than of crust. It is supported by ancillary evidence such as abundant grey, sooty carbon and high concentrations of sulphate (1–5 μg m^{-3}) in the aerosol[6] (both of which imply pollution), and high concentrations of ^{210}Pb in the aerosol[6,7] (which indicate that it is continental in origin). Tests at the surface (spring 1979) and aloft[8] have shown that this pollution does not originate on the North Slope; it is associated with air coming to Alaska from farther north. In analogy to the similarity of snows from various parts of the Arctic reported by Weiss *et al.*, we find a similar (pollution) aerosol at the widely dispersed Arctic sites of Spitsbergen, northern Norway, and northern Greenland during winter[6].

We therefore have two lines of evidence (aerosol and snow) which have arisen independently, are both solid and defensible, but offer divergent pictures of the Arctic environment. How can they be reconciled? Part of the difference for Barrow can be explained by recalculating snow–crust enrichment factors with Al rather than Mn as crustal reference element. Weiss *et al.* used Mn because it was common to all their snow samples. In general, however, Mn is enriched by factors of 3–10 in urban and rural atmospheres[9], presumably by pollution sources, and therefore should not be used as a crustal reference element wherever it can be avoided. (Of course, without knowing how much the Barrow aerosol is affected by pollution, it would seem reasonable to use Mn.) Concentrations and revised enrichment factors for the Barrow winter aerosol and the near-Barrow snows are shown in Table 1. These calculations, the basis for which can be justified from many aerosol samples[9], show that both V and Mn have modest but definite enrichments in the near-Barrow snows. But this recalculation removes only part of the discrepancy between Barrow aerosol and snow—V and Mn are still several times more enriched in the aerosol than in the snow, and all other elements except Ca have greater enrichments in aerosol than in snow. For Na, Mg and Ca, this difference may be marine-related, because the aerosol-sampling site was closer to the sea than were the snow-sampling sites. The other elements, however, are not marine in origin; their different enrichments must have another explanation.

We believe that the broad discrepancy between Arctic aerosol and Arctic snow is a genuine feature of the present Arctic environment. Possible explanations for it include: (1) formation of snow from a parent aerosol aloft whose composition differs from the surface aerosol; and (2) aerosol–snow fractionation during or after snowfall. We favour the second explanation for two reasons: first, we see little reason that the composition of the aerosol in such a remote, source-free area should change markedly with altitude. Second, formation of snow crystals by nucleation on clay minerals, such as are found at the centre of many or most polar snow crystals,[11,12], could fractionate snow chemically relative to aerosol. A central clay nucleus which contained 90% of the foreign matter if the ice crystal (estimated by M. Kumai, personal communication) would decrease enrichments in snow by the factor of 10 that is observed. We stress, however, that aerosol–snow fractionation in the Arctic is only a hypothesis.

We emphasise that whatever the eventual explanation, aerosol-snow differences in the Arctic imply, care is needed in interpreting ice and snow data atmospherically. Modern snows may not be automatically equated with modern aerosols; historical trends of deposition may not be immediately equated with historical trends of parent aerosol. Until thorough studies of the factors controlling the elemental composition of polar snow and ice are undertaken, these uncertainties will remain.

This work was supported by the Office of Naval Research (contract N00014-76-C-0435). Barrow aerosol samples were collected cooperatively with the NOAA GMCC program. We thank the staff of the GMCC Clean Air Observatory and the Naval Arctic Research Laboratory in Barrow, Alaska, for assistance. Aerosol samples from Spitsbergen and northern Norway were provided by the Norwegian Institute for Air Research; samples from Thule were provided by the Danish Air Pollution Laboratory and the Danish Meteorological Institute. Samples were analysed chemically at the Rhode Island Nuclear Science Center with assistance from R. D. Borys and T. J. Conway.

The 20-yr cycle in Greenland ice core records

CLIMATIC oscillations with a period of ~20 yr have been reported in North American winter temperature records[1,2], midwestern US drought indicators (ref. 3 and J. M. Mitchell, Jr personal communication), dendrochronological data[4], and sea-surface temperature anomalies[5]. These oscillations have mostly been attributed to double sunspot cycles, which seem to occur at about 22-yr intervals. Other possible causes include an 18.6-yr modulation of the diurnal and semidiurnal lunar tidal forces[5]. Critics[6,7] of these observations argue that such oscillations may only be an artefact of a red noise record, and are not uniformly present in a wide range of climatic data. It has also been argued that even if the oscillations are significant, their small amplitude renders them relatively unsuitable for climatic prediction[1]. However, if such oscillations prove to be real, identifying their nature and possible causes, even though their amplitude is small, can enhance our understanding of climatic change. To gain more insight into such 20-yr oscillations, we have examined characteristic oscillations in Greenland ice core oxygen isotope records. The results show that the strongest spectral peak occurs at a period of 20 ± 0.5 yr with a statistically significant amplitude. This period is essentially the same as that found in eastern North American winter temperatures[1]. Moreover this 20-yr oscillation is found to be coherent in phase with the dominant variation in the Sun's motion about the centre of mass of the Solar System. This motion has been hypothesised[8] to be closely linked with sunspots. On the basis of these observations we speculate here that a 20-yr oscillation may be a more fundamental solar and/or climatic oscillation than the nominal 22-yr cycle often mentioned.

Because dating procedures[9] are highly accurate, climatic time series obtained from Greenland ice core records are especially suited for detailed spectral analysis. From recent cores several well-dated coincident oxygen isotope records spanning 728 yr (1244–1971) have been obtained. These data supply an adequate-length time series for resolving frequencies accurately, while still yielding a typical sampling interval of <0.2 yr. These records do, however, contain significant amounts of spatially incoherent non-climatic noise due to depositional irregularities. In an analysis of several shallow cores separated by <60 km, Reeh *et al.*[10] found this non-climatic component accounted for about 50% of the variance of the isotopic records and generally had a 'red' spectral content. This 50% figure has also been verified using deeper (100 m) cores (N. Reeh, personal communication). Because of this depositional noise, the significance of spatially coherent oscillations in the records can be substantially enhanced by averaging several records at different locations.

Although not critical for this study, it should be noted that the precise meteorological significance of the isotopic records is not determined. In Greenland, correlations suggest that the isotopic records indicate atmospheric temperature variations[11]. Comparison of one of these records[12] with temporally smoothed Icelandic and central England temperatures supports this interpretation. However, the isotopic values are possibly indicative of shifts of storm tracks, which in turn tend to modify the source of the precipitation.

For analysis here, coincident portions of three cores were used: Crete [71.12° N, 37.32° W], Milcent [70.31° N, 44.58° W] and Dye 3 [65.18°N, 43.82° W]. All three of these cores were obtained as part of the International Greenland Ice Sheet Program (GISP). To reduce the depositional noise, oxygen isotopic records from these three cores were averaged to form a combined time series for portions of the analysis.

Of the core sites Milcent is on the western side of the ice divide, Dye 3 on the eastern side and Crete effectively on the divide. Primarily because of this, Dye 3 and Milcent tend to receive precipitation from different directions, whereas Crete probably receives precipitation from either direction[13]. Also, Dye 3 is further south, and hence the core contains more melt features which yield some measure of summer temperature[14].

To analyse these isotopic records spectrally both conventional lagged product[15] and maximum entropy[16] (ME) spectral analysis methods were used. Conventional techniques allow statistical confidence levels for the spectral peaks to be estimated, while the ME techniques aid in precise determination of frequencies and power. For the maximum entropy analysis, the Burg algorithm as formulated by Andersen[17] was used to estimate a minimum delay autocorrelation function from which the ME spectrum was calculated. In all cases 2 yr non-overlapping averages were taken before analysis in order to display the low frequencies better and to reduce the noise level. The use of such averages was supported by analyses of the whole 1 yr averaged combined record which yielded low frequency

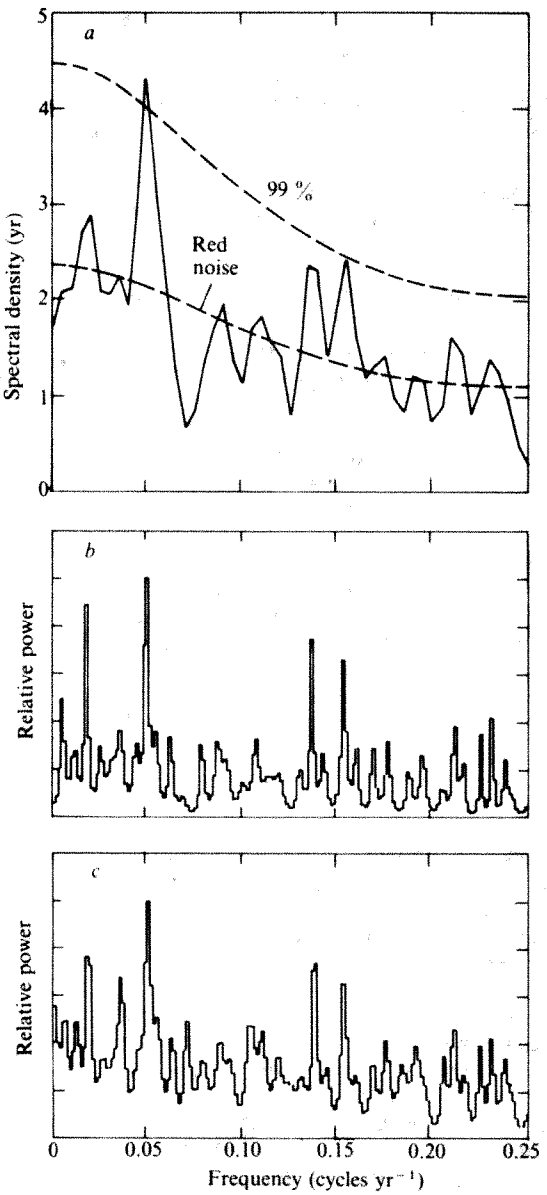

Fig. 1 Spectral densities of ice core oxygen isotope records. Two-year averaged data were used for the analysis. *a*, *b*, The conventional and ME spectra of the combined isotopic record formed by combining the three core records from 1244 to 1971. *c*, The average spectrum of the three records taken separately. In *a* 50 lags were used to analyse a 364-point time series of 2-yr averages, together with a Hamming Spectral Window. Twenty degrees of freedom were used in estimating confidence limits. This estimate was based on the expression $2.7\ T/M$ (ref. 15) where T is the record length and M is the auto covariance length.

Table 1 Periods and relative power of ME spectra of combined Crete, Milcent, Dye 3 oxygen isotopic ratio record

Whole record (1244–1971) (80 filter wts)		Bottom half of record (1244–1607) (40 filter wts)		Top half of record (1608–1971) (40 filter wts)	
Period	Relative power	Period	Relative power	Period	Relative power
20.00	8.17	6.47	16.97	20.36	17.28
54.41	5.88	28.35	12.73	7.35	12.51
6.53	5.59	56.67	10.00	51.27	11.09
7.31	5.00	19.73	9.75	144.20	7.52
183.70	4.27	5.28	6.36	9.32	6.87

2-yr averages sampled every 2 yr were used in the analysis.

(≤ 0.25 cycles yr^{-1}) results almost identical to those obtained from 2-yr averaged data.

Figure 1*a* shows the lagged product spectrum of the combined isotopic record. Figure 1*b* is the ME spectrum of the combined isotopic record, and Fig. 1*c* is an average ME spectrum obtained by finding a common unit prediction filter for all three records—a straightforward extension of the Burg algorithm. (This average spectrum is essentially the sum of the individual time series spectra.) The primary difference between the 'combined' spectrum and the 'average' spectrum is that in the 'combined' spectrum cycles with phase differences will cancel, whereas in the 'average' spectrum phase differences from record to record do not matter. Note that both ME spectra have similar dominant peaks with the 'combined' spectrum having less noise. This indicates a phase coherence between the dominant oscillations in the different records. This phase coherence was also verified directly for the 20-yr cycle by direct correlation of bandpassed individual records.

The dominant feature in these spectra is a pronounced peak with about a 20-yr wavelength. As demonstrated in Fig. 1*a*, the 20-yr peak is statistically significant at the 99% level when compared with red noise. Based on this spectrum it seems unlikely that this peak is simply an artefact of simple 'persistence' in the climate (which in the simplest case is a first order Markov process with a red noise spectrum[18]).

To determine more precisely the frequency of this peak, the analytical integration procedure of Johnsen and Andersen[19] was used. In this method, the analytical expression for the maximum entropy spectrum is integrated using residue theory. This procedure gives a precise value for both the power and frequency of a given peak. Table 1 lists the first five peaks (ordered by their power) for the average isotopic record. Also listed are the first five peaks in the bottom and top halves of the record. While there is some scatter in these results we feel they conservatively place the period of the 20 yr oscillation at 20.0 ± 0.5 yr. This result was also verified by higher resolution conventional lagged product spectra with a frequency resolution of 0.0025 cycles yr^{-1}.

This period agrees with a 20-yr period found in eastern North American January temperatures by Mock and Hibler[1]. It is, however, in contrast to a 23-yr cycle found by Bain[20] in central England temperatures and a 22-yr spectral peak in Bristlecone pine data found by Epstein and Yapp[4]. (Epstein and Yapp[4], however, used 10-yr averaged data, which could effectively filter out a 20-yr cycle. For example, taking 10-yr averages of the combined isotopic record reduced the 20-yr cycle amplitude and shifted it to 21 yr.) This period also contrasts somewhat with a 20–22 yr drought cycle in the Midwest suggested by Roberts and Olsen[3] and found in tree-ring drought data by Mitchell, Stockton and Meko (personal communication).

One of the main reasons that researchers favour a 22-yr cycle in climatic records has been the belief in possible weather links to a hypothesised 22-yr double solar cycle. In principle, this cycle arises because of different magnetic polarities[21] of sunspot cycles which, in observations over the past 90 yr, have been found to reverse in alternate cycles nominally occurring at 11 yr intervals. It also appears that magnetic activity is consistently different in adjacent cycles[21]. Pittock[7] has argued that no link between solar cycles and climatic change has been established, and a 20-yr rather than a 22-yr cycle could support his scepticism. By this view the 20-yr cycle in the ice core data could be simply a resonance in the climate system. However, examination of available sunspot data indicates that it is difficult to ascertain the precise period of the 'double solar cycle'. Consequently, an alternative hypothesis which, in our judgement, cannot be ruled out is that a double solar cycle is occurring at 20 yr rather than 22 yr. Under this hypothesis the relatively irregular sunspots could be viewed as a stochastic manifestation of some more regular 20-yr cycle. Certainly such a coincidence would not prove a link between solar variations and the ice core records, but it would at least provide a possible forcing at the correct frequency.

Although he performed no spectral analyses, Jose[8] indirectly advanced the hypothesis of a 20-yr solar oscillation in a detailed calculation of the Sun's position relative to the Solar System centre of mass. In particular, Jose compared various solar orbital parameters (which typically vary with a 20-yr period) with sunspot data. He found that if, in early sunspot records without polarity observations, the polarities of adjacent sunspot cycles were in special cases not reversed, then excellent correlation with the Sun's motion could be obtained. Note that such a deterministically forced theory of sunspots, while not necessarily in agreement in period, is consistent with a recent suggestion by Dicke[22] that the sunspots are irregular manifestations of a more regular phenomenon.

To compare the period and phase of the solar oscillation at 20 yr with the ice core oscillation, we have made a simple (but less precise than Jose) calculation of the Sun's orbital parameters. We assume, as a first approximation, that the planetary orbits are circular, and in the same plane, then by conservation of momentum (that is $\sum_i m_i \dot{\mathbf{r}}_i = 0$) the position of the Sun relative to the centre of mass of the Solar System may be easily estimated. Using planetary data from Allen[23], we calculated various orbital parameters over the same 728-yr period spanned by the ice core data. Figure 2 shows a ME spectrum of the rotation rate $[(\dot{x}\ddot{y} - \dot{y}\ddot{x})/(\dot{x}^2 + \dot{y}^2)]$ of the centre of the Sun about its instantaneous centre of curvature. This parameter is chosen because it would be a portion of the effective 'coriolis' parameter seen by any rotating turbulence in the convective zone of the Sun. (Parameters such as the Sun's velocity do, however, yield similar spectra.) The spectrum is strongly dominated by a 19.8-yr peak. This peak physically arises due to the synodic period of Jupiter and Saturn, being ~19.85 yr. There is also a secondary weaker peak at ~11.9 yr which corresponds closely to the 11.86 yr orbital period of Jupiter.

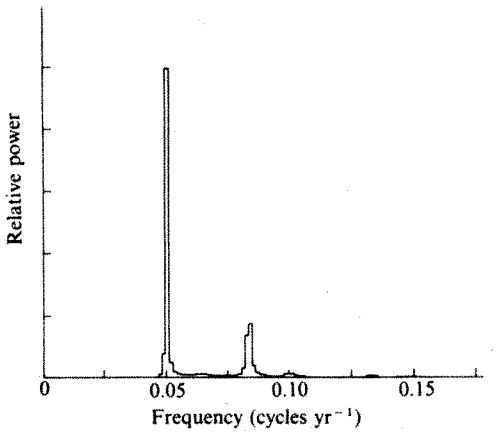

Fig. 2 Spectrum of rotation rate of the centre of the Sun about its instantaneous centre of curvature (relative to a fixed coordinate system at the centre of mass of the Solar System).

Table 2 Periods and relative power of the sunspot record (1699–1971) using various polarities

Single cycle (polarity ignored)		Double cycle (polarity reversed in adjacent cycles)		Double cycle using Jose's polarities	
Period	Relative power	Period	Relative power	Period	Relative power
10.93	33.12	21.99	70.22	20.12	55.82
9.99	20.22	18.37	12.21	24.24	18.76
93.74	11.68	26.39	2.89	30.73	6.75
12.15	7.23	15.87	2.29	13.94	3.81
50.37	6.61	13.71	1.96	16.11	3.76

Annual mean values together with 100 filter wts were used in the analysis.

To establish the phase drift of the isotopic cycle relative to the Sun's 'coriolis' variations, we correlated a narrow frequency band of the isotopic record with the solar motion. To construct this bandpassed record the procedure of Ulrych *et al.*[24] was used. In particular the record was first extended forwards and backwards using ME, and then bandpass filtered, using a filter[25] with pass band from a period of 21.05 yr to 19.05 yr. Since the ratio of this band width to the Nyquist frequency is about 0.02, we estimate the degrees of freedom to be about 1 per 100 yr. In both the bottom and top halves of the record the best correlation occurred at a 180° phase shift (within 2 yr), indicating a good phase coherence. While this phase coherence could be a statistical fluke, it suggests a deterministic forcing rather than an internal stochastic oscillation.

To demonstrate the effect of Jose's hypothesised polarity on the sunspot spectra, we used the Johnsen–Andersen[19] spectral integration technique to determine the first five peaks in the various sunspot records (see Table 2). As can be seen, using Jose's polarities the inverted cycle yields a sharp 20-yr peak. Note also that in addition to an 11-yr cycle there is a strong 10-yr cycle in the normal (polarity ignored) sunspot record[21].

Studies by Eddy[26] have suggested that the occurrence of sunspots may be quite irregular, with the sunspots even disappearing for several decades. This fact in conjunction with the uncertainty in periods exhibited by Table 2 suggests that it is probably not possible to establish whether a 'double solar cycle' is occurring at 20 or 22 yr from available sunspot records alone.

In conclusion, the results presented here demonstrate a dominant oscillation in Greenland ice core isotopic records at a period of about 20 yr. While we know of no causal link, such a period also coincides with the Sun's motion relative to the centre of mass of the Solar System. This motion has been suggested to correlate with sunspot variations. On the basis of these observations we speculate that a 20-yr oscillation may be a more fundamental climatic variation than the nominal 22-yr 'solar cycle'.

We thank Dr N. Reeh for discussions on ice core spectra, Dr S. Mock for comments on sunspot spectra, Dr N. Andersen for suggesting a simple way to calculate solar motions, Dr W. St. Lawrence for helpful comments, and Professor W. Dansgaard for encouragement. This work was supported by the DA and the NSF.

Combined structural and chemical analysis of 3,800-Myr-old microfossils

CELL-like inclusions detected in the cherty layers of a quartzite, which is part of the Isua series in South-west Greenland, consist of biological materials, according to analyses by Raman laser molecular microprobe. The available radiometric data place the age of the sequence at around 3,800 Myr[1]. Thin sections of our specimens were taken in their primary positions within the rock matrix. The material used was compact and unweathered. No maceration, etching, impregnation or other methods were applied which might have produced artefacts.

About 100 well preserved specimens noted in the material were sealed within the quartz grains or in the silica cement in a three-dimensional condition (Fig. 1*d*, *f*). This sealing apparently results from a synsedimentary permineralisation caused by colloidal silica, which subsequently crystallised to form chalcedony. Our observations suggest that these specimens are primary constituents of the sediment, and are not contaminants from a later time.

The fossils occur as individual unicells (Fig. 1*c*), filaments (Fig. 1*a*, *b*) or cell colonies (Fig. 1*e*). Cells and cell families are usually surrounded by multilaminate sheaths which show a characteristic laminar structure. All specimens observed apparently belong to the same kind of organism, named *Isuasphaera*[2].

The individual cells are more or less ellipsoid in shape. The mature cells range between 20 and 40 μm in diameter. The cell encloses a more or less globular hollow which is partly filled with organic matter (p in Fig. 1*e*). Apparently, this filling is a remnant of the former protoplasm which has been degraded during fossilisation. A vacuole is often contained in the cell lumen (v in Fig. 1*c*).

The mode of reproduction indicated resembles the kind of budding known in recent yeasts. Figure 2 shows the characteristic stages of reproduction frequently observed in the material.

The best way of confirming the biogenicity of a fossil residue is by relating morphology and chemistry. In practice, the chemical proof becomes a problem: most of the conventional analytical techniques require powdering and leaching of the rock samples. Consequently the results obtained are representative of the whole-rock bitumen and not specifically the enclosed microfossils.

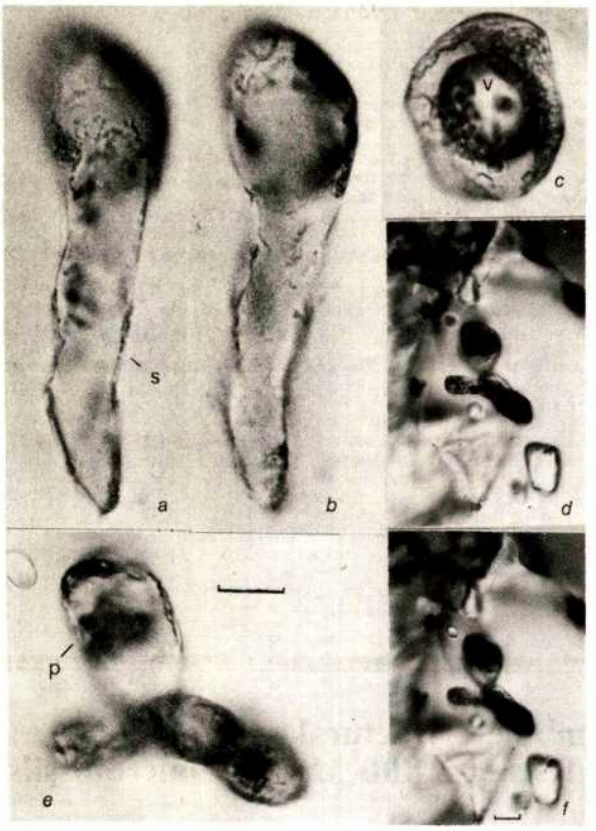

Fig. 1 *Isuasphaera isua* Pflug, 1978 Isua quartzite Greenland 3,800 Myr *a*, *b*, Filament: s, sheath; *c*, single cell: v, vacuole; *d–f*, ramified colony: p, organic cell filling; *d*, *f* are two foci, showing the specimen in its primary position within a quartz grain (bright). Magnifications: *a–c*, *e* ×900; *d–f*, ×290. Scale bar in *e* and *f*, 10 μm.

Individual and non-destructive analysis of microfossils in rocks has proved possible with the Raman microprobe analyser Mole[3]. This is a new physical method of microanalysis, based on the vibration spectra characteristic of polyatomic structures. A focused laser beam excites the sample. The light diffused by the Raman effect is used to identify and locate the molecular constituents present in the sample[4].

For the present work only one of the possible modes of the Mole was used: the monochannel spectrometer Raman mode. A light-optical microscope investigates the interesting structures in the sample and where the laser beam should be directed. The measuring spot can be restricted to ~1 μm in diameter. The diffused light is collected and analysed by a double monochromator equipped with holographic gratings. It is then received by a photomultiplier, amplified and recorded on paper as a function of wavenumber. The light used for excitation was the green line (5,145 Å) of an ionised argon laser.

Unmounted thin sections, ~40–100 μm in thickness, were taken from the rock samples. Polishing powder and distilled water only were applied to the slides during preparation. Any contact with organic substances was carefully avoided.

Thirteen well preserved specimens were selected for the analysis. They were all located below the surface cut and were completely enveloped by the mineral matrix. Separated analyses were made of different portions of the individuals—the cell interior, the cell wall and the enveloping sheath. Control measurements were extended to the mineral vicinity of the specimens and to the surface of the slide.

Two different types of spectra were obtained. One (Fig. 4) is typical of the dark brownish substance composing sheath, cell wall and cell filling (s, p in Fig. 1*a*, *e*), the other spectrum is typical (Fig. 5) of the cell vacuole (v in Fig. 1*c*).

Hydrocarbons of high aromatisation and condensation similar to those present in asphaltites are indicated by most of the spectra obtained from cell walls and fillings (Fig. 4*a–c*). Some spectra differ from this type by developing a stronger intensity at 1,360 cm^{-1} (Fig. 4*e*, *f*). Such patterns are characteristic of

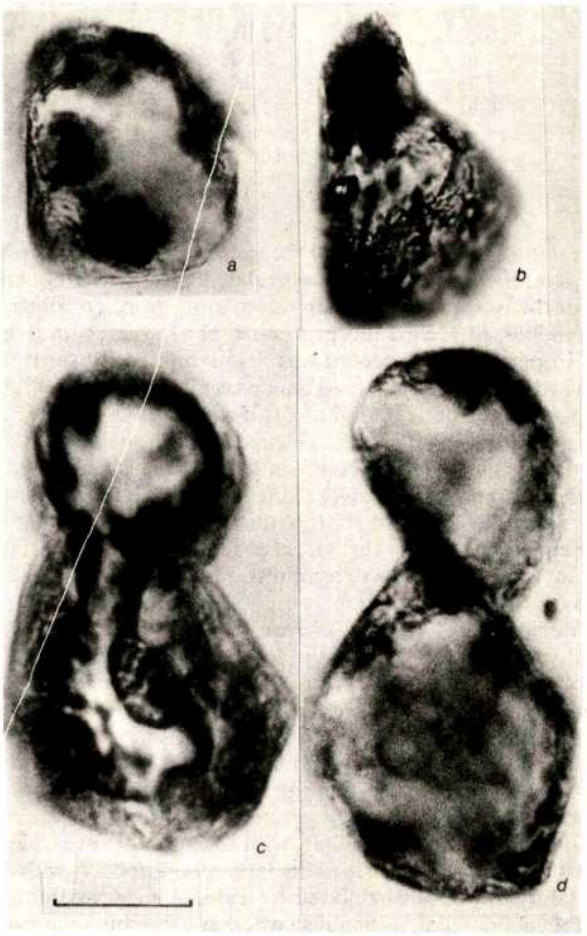

Fig. 2 *Isuasphaera* in different stages of budding (compare Fig. 3). Scale bar, 10 μm.

amorphous carbon produced by charring of organic material. It is therefore possible that some graphite may also be present in the *Isuasphaera* matter. The Raman spectrum of graphite[5] is characterised by a strong, sharp line at 1,580 cm^{-1}, and clearly differs from the larger band formed in the *Isuasphaera* spectra at about 1,595 cm^{-1}. Another difference is the band at 1,360 cm^{-1} which seems to be narrower in the graphite spectrum than in the *Isuasphaera* spectrum. Thus, graphite can account for, at most, only part of the fossil matter. It can be concluded from the analyses that *Isuasphaera* consists of organic material which is partly present in a carbonised condition, partly in a high rank of coalification very similar to a final stage of graphitisation. This is in accordance with the metamorphic condition of the enclosing rock which seems to be in the range of an upper greenschist facies[6].

Characteristic Raman spectra were obtained from two cell vacuoles of *Isuasphaera* (Fig. 5). In these, we find the typical lines of organic functional groups. A stretching vibration of the carbonyl group C=O appears at 1,745 cm^{-1}. The high wavenumber corresponds to that of an ester carbonyl. Indications of the presence of an ester are also found with the line at

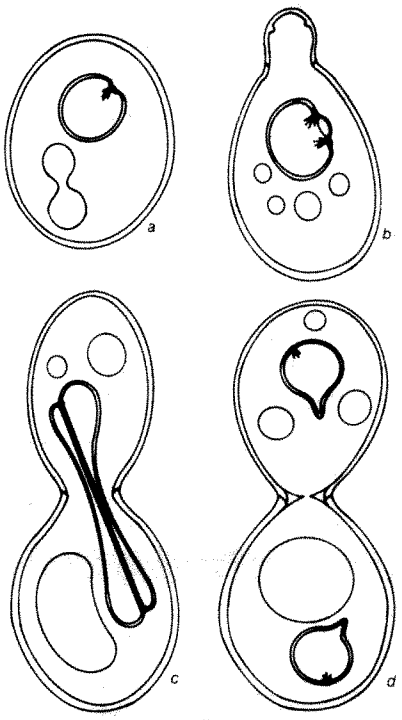

Fig. 3 Stages of a budding yeast cell: n, nucleus, v, gas vacuole (simplified after Matile *et al.*[10]).

850 cm^{-1}, which is the region of stretching vibration νC—C adjacent to a carbonyl carbon bond. Another indication is the high frequencies of νC—H vibrations near 3,000 cm^{-1}. An intense line at 1,460 cm^{-1} shows that a large amount of aliphatic hydrocarbons is present because the line corresponds to the deformation vibrations of CH_3 and CH_2 groups. The same groups are responsible for the broad signal at about 3,000 cm^{-1} which is a region in which the C—H stretching vibrations appear. The highest peak is a doublet at 2,950 and 2,967 cm^{-1}; a position which is typical for C—H vibrations in an electronegative environment corresponding to that of an ester function.

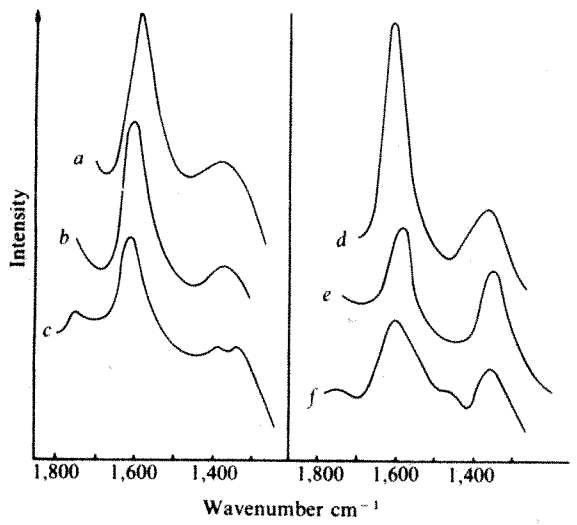

Fig. 4 Raman spectra obtained from cell wall and cell filling of *Isuasphaera* (*b–f*) compared with that of resinous asphaltite from Boscan (*a*).

Between 1,460 and 1,745 cm^{-1}, no significant lines for C=C double bonds occur.

We believe that the preservation of the vacuoles is due to the special conditions in the cherts. Normally, the volatile compounds set free from the mother bitumen during metamorphosis escape through pores and cracks of the rock. However, degassing cannot take place from material which is hermetically sealed in a quartz grain. Here the volatile fractions produced remain trapped in the matrix and after cooling, condense at the place of their origin, that is, at the cell lumen or nearby.

Structural comparisons have shown[2] that *Isuasphaera* conforms with recent asporogenous yeasts in all its preserved morphological properties, such as size, shape, structure of the cell wall and sheath, mode of growth and reproduction (Figs 2 and 3). But in the present context budding is not an exclusive

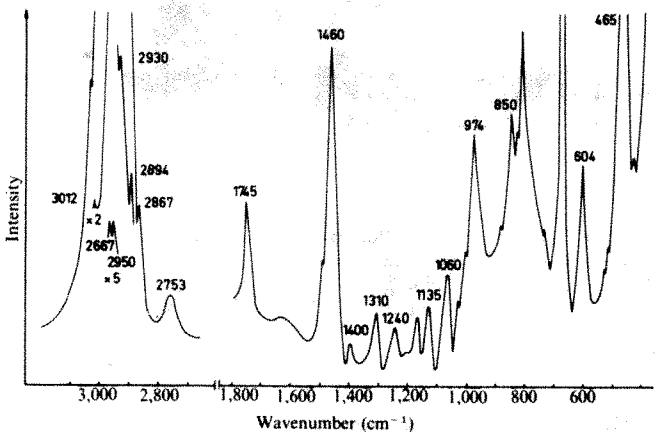

Fig. 5 Raman spectrum obtained from the cell vacuole of *Isuasphaera* (v in Fig. 1*c*).

characteristic of living cells. Multilateral budding, which is not dissimilar to that of *Isuasphaera* is, for example, known from Fox's microspheres—the artificial protein aggregates produced by certain laboratory experiments (Fig. 6). Because of their interesting budding abilities, the microspheres are often considered as a possible model for the hypothetical protocell[8].

However, fossil *Isuasphaera* differs from the microspheres in a series of specific features showing that it was not an abiotic product but a true organism. The exterior multilaminate sheath enveloping the *Isuasphaera* cell can only be understood as a product of biological activity.

Metabolic production is also indicated by the esters filling the cell vacuole of *Isuasphaera* (Fig. 4). Similar fat globules are found in recent yeast cells. They commonly make up 30–40% of the dry weight of the organism and reach 50–60% in some genera. Compounds of the lipid fraction are known to be resistant to decomposition and can, in the proper environment, last for long periods of time. They are also known to be a main source of the petroleum hydrocarbons.

There is little doubt that *Isuasphaera* is an organism. This is indicated by the morphological and chemical details. A problem results from the similarities between *Isuasphaera* and recent yeasts. If we conclude that yeasts existed during Isua times, life must be much older than 3,800 Myr. According to our present knowledge, the Earth's sphere formed about 4,450 Myr ago[9]. Consequently biophile conditions, implying a solid crust, cool temperatures and liquid water cannot have been realised on Earth earlier than about 4,400 Myr ago. The time span of roughly half a billion years, however, appears too short for the evolution from a simple organic compound to a eukaryotic organism to have occurred.

Fig. 6 *Isuasphaera* (*b*) compared with Fox's microsphere (*a*), an artificial budding structure consisting of protein, which has often been considered as a model of the hypothetical protocell (*a* from 8). Scale bars in *a*, 0·5 μm; *b*, 10 μm.

However, the classification of *Isuasphaera* to yeasts or other eukaryotes is uncertain. The question of whether an organism is an eukaryote or not can hardly be decided without knowledge of the protoplasm which no longer shows structural details in its fossil condition. The example of the microspheres (Fig. 6) indicates that cellular budding does not have to be a very complicated process nor does it have to depend on a complicated endocellular apparatus.

Thus, it seems that *Isuasphaera* in spite of its yeast-like appearance may occupy an evolutionary level far below that of eukaryotes. Consequently, *Isuasphaera* may represent a half-way line between a microsphere-like protobiont and subsequent evolution.

We thank Dr P. W. U. Appel, and Dr M. Schidlowski, Mainz, FRG, for the rock samples. The work is part of the DFG-project Pf 21/27.

An early Cretaceous terrestrial crocodilian and the opening of the South Atlantic

THE discovery in the lower Cretaceous of Niger of *Araripesuchus*, a small terrestrial crocodilian previously known only from Brazil, corroborates the existence of an African–South American faunal community until the Aptian. We show here that this provides additional evidence that an open seaway connecting the northern and southern parts of the Atlantic was not established until well into the early Cretaceous.

Among the abundant remains of terrestrial and freshwater vertebrates found (by P.T.) in the vast early Cretaceous fossil locality of Gadoufaoua (northeastern part of the Republic of Niger)[1] are those of a small short-snouted crocodilian. They were first discovered in 1966, and have been mentioned[1] as those of a 'brevirostrine crocodilian'. These specimens include incomplete skulls and lower jaws, vertebrae, dermal scutes, and limb bones. After acid preparation (by E.B.) of the very hard sandstone matrix, they were first found to belong to the genus *Araripesuchus*, a notosuchian crocodilian previously recorded by Price[2] from the early Cretaceous of Brazil.

The most significant specimen is a partial skull with the lower jaw still attached (Fig. 1); the part of the head located behind the orbits has disappeared. This skull is small: its complete length must have been about 12 cm, which indicates a crocodilian about 90 cm long. The snout is remarkably short and comparatively broad. The external nostrils are located in a very anterior position. The maxillae are somewhat 'swollen' behind their junction with the premaxillae. There is a large well defined antorbital fenestra, bordered anteriorly by the maxilla, posteriorly by the lacrymal. The orbits were large. A palpebral bone is present. In the upper jaw, there are 4 teeth in the premaxilla and 11 in the maxilla. The third premaxillary tooth and the third maxillary tooth are enlarged. The back teeth of the maxilla are small, laterally compressed, and have a rounded apex. The internal nares are large and located between the palatines and the pterygoids in a typically mesosuchian position. The lower jaw has a moderately long symphysis, in which the splenials take part. Postcranial remains indicate that the vertebrae are amphicoelous and that a dorsal and a ventral armour of dermal scutes were present.

These characters are consistent with the inclusion of this form in the mesosuchian infraorder Notosuchia and the family Uruguaysuchidae, as defined by Gasparini[3]. The Notosuchia are a group of small, short-snouted mesosuchian crocodilians, represented in South America by the families Uruguaysuchidae (early Cretaceous and beginning of the late Cretaceous) and Notosuchidae (late Cretaceous)[3]. The Libycosuchidae[4], from the Cretaceous of Africa[5], could also be referred to this infraorder. Closer comparison shows that the fossils from Gadoufaoua are very similar to the uruguaysuchid *Araripesuchus gomesii* Price, 1959, known from a skull and lower jaw found in the Santana Formation of northeastern Brazil[2]. The resemblances (Fig. 2) are such that it seems safe to refer the African form to the genus *Araripesuchus*. However, some minor differences in the shape of the teeth (which in the African form are reminiscent of *Uruguaysuchus* from the Cenomanian of Uruguay[6]) and in their relative sizes, as well as in the shape of the antorbital fenestra, will probably justify the suggestion of a new species, closely related to *A. gomesii*. This is thus the first record of an uruguaysuchid in Africa, and it has significant palaeobiogeographical implications.

The Elrhaz Formation of Niger, which has yielded the African *Araripesuchus*, and the Santana Formation of Brazil, from which comes the only known specimen of *A. gomesii*, are approximately of the same age. According to stratigraphic and palaeontological evidence[1], the Elrhaz Formation is probably of late Aptian age. The age of the Santana Formation has been disputed, but recent research both on the invertebrate[7] and verte-

0028-0836/79/320486-02$01.00 © Macmillan Journals Ltd 1979

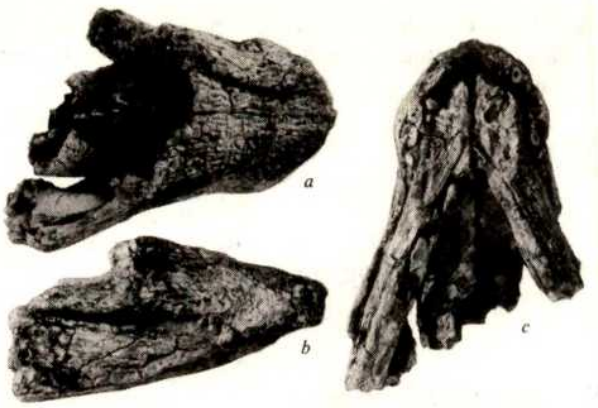

Fig. 1 *Araripesuchus* sp. from the Aptian Elrhaz Formation of Gadoufaoua, Republic of Niger. Incomplete skull and lower jaw collected by P.T. Muséum National d'Histoire Naturelle, Paris, No. GDF 700. *a*, Dorsal view; *b*, lateral view, showing the antorbital fenestra; *c*, ventral view, showing the internal nares. Total length of specimen: 90 mm. Photographs by D. Serrette.

brate[8] faunas tends to refer it to the late Aptian[9]. The discovery of *Araripesuchus* in the Aptian of Niger provides further evidence that the Santana Formation is not of late Cretaceous age, as was formerly believed.

The occurrence of very closely related species of *Araripesuchus* in the Aptian of Niger and Brazil also provides additional evidence of the existence of a terrestrial and freshwater vertebrate fauna little if at all divergent between Africa and South America until late in the early Cretaceous. This was already indicated by the presence of several very closely related forms (including freshwater fishes and the giant crocodilian *Sarcosuchus*) at Gadoufaoua and in the freshwater deposits, of probably Aptian age, of the Bahia/Reconcavo basin, on the eastern coast of Brazil[10]. We interpreted this fact as evidence that South America and Africa had not yet completely separated in the Aptian[10]—that there was no complete marine connection between the North Atlantic and the South Atlantic at the time—a hypothesis supported by studies on the ostracod faunas of the early Cretaceous coastal basins of Gabon and Bahia[11]. Note that the anatomy of the Notosuchia indicates that these

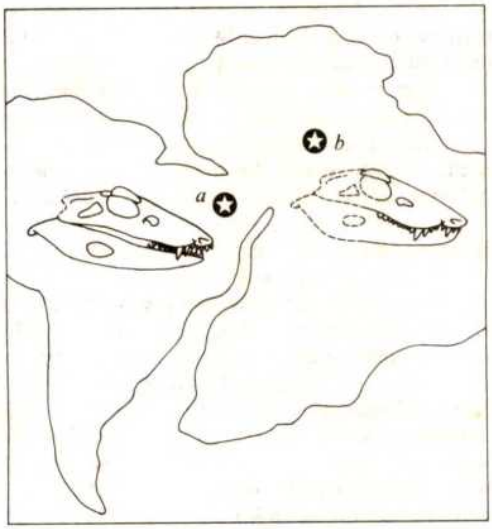

Fig. 2 Geographical distribution of the genus *Araripesuchus* in the Aptian. *a*, *Araripesuchus gomesii* Price, 1959, from the Santana Formation, Chapada de Araripe, northeastern Brazil (after Price[2]). *b*, *Araripesuchus* sp., from the Elrhaz Formation of Gadoufaoua, Tegama basin, Niger. Length of the lower jaw in both about 130 mm. Position of South America and Africa in the late Aptian after Förster[14].

small crocodilians were adapted to a terrestrial, somewhat 'mammal-like', way of life; *Araripesuchus* certainly could not cross any large area of saltwater.

Evidence relating to the date of the opening of a continuous seaway between Africa and South America has been based largely on the distribution of ammonites. On the basis of these kind of data, Reyment[12] concluded that a complete marine connection allowing a faunal interchange became established in the middle Turonian. Kennedy and Cooper[13] have then claimed that such a connection existed as early as the late Albian, a conclusion also supported by Förster[14] and Förster and Scholz[15]. Palaeobathymetric[16] and sedimentological[17] studies support the hypothesis of the establishment of a marine connection at the end of the early Cretaceous. These views, which suggest that a seaway separating Africa from South America came into being in the Albian, about 110 Myr ago, are consistent with our conclusions based on the Aptian terrestrial faunas of these continents. However, in a recent collection of palaeocontinental maps[18], Smith and Briden favour an earlier date—the beginning of the Cretaceous—for the opening of the South Atlantic and the separation of Africa from South America. We believe that palaeontological evidence based on the distribution of terrestrial and freshwater vertebrates, reinforced by the discovery of the crocodilian *Araripesuchus* in Niger, shows that a land connection between South America and Africa may still have existed as late as Aptian times. This obviously favours a comparatively late opening of the South Atlantic, at the end of the early Cretaceous.

Toxicity induced in the tobacco horn-worm (*Manduca sexta* L.) (Sphingidae, Lepidoptera)

INSECTS feeding on toxic plants demonstrate three fairly distinct types of life-style[1–3]. There are cryptic species, which metabolise or rapidly excrete the toxic substances present or avoid their ingestion by selective feeding; aposematic or warningly coloured species which store plant toxins in their tissues unchanged or slightly modified[4]; and aposematic species which superficially resemble or mimic toxic species—without actually storing poisonous plant products—or those warningly-coloured

non-storers which secrete their own toxins. It is generally agreed that the cryptic life-style is more 'successful' than either of the other two, which are relatively rare, and it is difficult to envisage the evolutionary steps necessary to enable a species to change to the more hazardous warning life-style. If, however, circumstances favour a switch to certain toxic host plants, a cryptic insect is frequently destined to become warningly coloured[1,5]. On the basis of experiments with *Manduca sexta*, the tobacco horn-worm, we suggest that the evolution of an aposematic poisonous insect, from the more common, harmless, cryptic type, may simply involve a change to a related food plant containing different toxic properties from those of its usual host. Storage and the acquisition of toxicity and warning colour could follow this crucial switch.

In the Sphingidae there are several examples of aposematic larvae which feed on toxic plants, such as *Plumeria* (ref. 6 and unpublished results of M.R. and N.M.), but which give rise to cryptic, non-poisonous adults. This suggested that storage, even if temporary, sometimes occurs in this group. It seemed more likely that a cryptic insect such as *Manduca*, which excretes toxins rapidly[7,8], rather than those which metabolise them, would be able to switch more readily to tissue storage.

We reared *M. sexta* (from hatching to the pupal stage) on the abnormal food plant belladonna (*Atropa belladonna* L.), and controls on leaves of tobacco (*Nicotiana tabacum* L.) or standard Yamamoto[9] artificial diet lacking leaf powder. Between one and three of the pupae resulting from belladonna-reared larvae were then fed to each of six hens, all of which died within 1–7 d. Two of the tobacco-reared specimens, and 14 of those fed on artificial diet (controls) were eaten by two hens, neither of which suffered any visible ill effects and continued egg-laying throughout the 7 d of the experiment.

Extracts of four belladonna-reared pupae (3.354–4.207 g each) were injected intraperitoneally into laboratory mice, of which three out of four died within 20–25 h[6]. Extracts of pupae reared on tobacco and artificial diet failed to elicit any visible response in the mice.

Analysis of the belladonna-reared pupal stage revealed the presence of atropine in the body tissues (Table 1) and both atropine (I) and two metabolites (II and III) were found in larval frass. The pupae of *M. sexta*, when reared on belladonna, therefore contain lethal toxins.

We thank Carroll Williams for *M. sexta* eggs and Brian Gardiner and Catherine Godfrey for assistance with rearing caterpillars.

Retinal site of transient tritanopia

WHEN the eye is adapted to a bright yellow light, a marked loss of sensitivity for short-wavelength stimuli occurs in the first few seconds after extinction of this light. This phenomenon was first reported by Stiles[1] and has been termed transient tritanopia by Mollon and Polden[2]. The latter authors suggest that this apparent suppression of the short-wave sensitive cones (hereafter called blue cones) during rapid dark adaptation is effected through inhibition by the recovering long- and middle-wave sensitive cone mechanisms[2] (hereafter called red and green cones, respectively). In this study we attempted to localise the site of blue cone inhibition through intra-retinal recordings from the intact rhesus monkey eye. We found transient tritanopia to be absent at the receptor level but present at the b-wave level, and we conclude that transient tritanopia originates at a site between the receptors and the bipolar cells, probably at the horizontal cells, as was earlier hypothesised by Augenstein and Pugh[3].

The signal that is recorded with a microelectrode positioned in the central fovea of a rhesus monkey eye, the local electroretinogram (LERG), consists mainly of the positive-going cone late receptor potential (LRP), also termed PIII, with a superimposed negative-going b-wave[4], representing activity at the bipolar cell level[5,6]. Figure 1 shows typical waveforms of responses to 447-nm and 551-nm flashes in two conditions. In the first condition, 'during yellow', a 10^5-troland yellow/orange background was present. The second condition, 'after yellow' (the transient tritanopia condition), is in the dark, shortly after extinction of the yellow/orange background. In the lower panels (Fig. 1), the 551-nm flash response 'after yellow' shows a large increase of both receptor potential and b-wave, compared with the 'during yellow' condition (note the difference in vertical scale). This increase reflects the removal of a desensitising field, that is, switching off the background. The situation is different for the 447-nm flash responses (Fig. 1, upper panels), where the removal of the background field leaves the receptor potential unaltered, but virtually abolishes the b-wave.

0028-0836/79/320488—03$01.00

© Macmillan Journals Ltd 1979

To assess which cone systems are involved in evoking these responses, the spectral sensitivities of both LERG components in the two conditions were determined for three monkeys (Fig. 2*a*, *b*). Spectral sensitivity is defined as the inverse of the flash intensity necessary to evoke a criterion response. Figure 2*a* gives the receptor potential data. The data points were fitted with the blue cone spectral sensitivity function[7] in the short-wavelength region and the CIE standard photopic spectral sensitivity function for a 10° stimulus[8] ($V_{10,\lambda}$) in the rest of the spectrum. The low sensitivity of the long- and middle-wavelength-sensitive cones relative to the blue cones is apparent

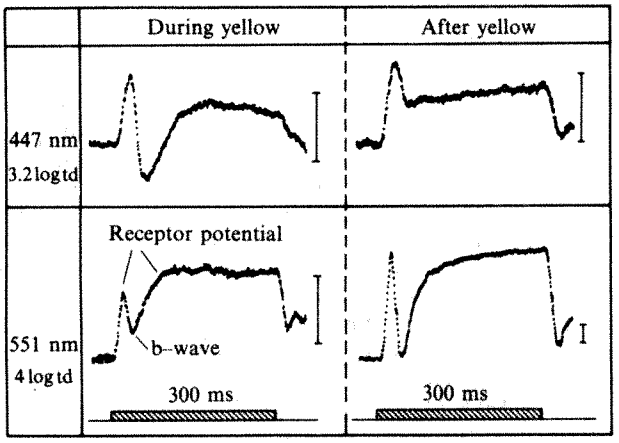

Fig. 1 Responses obtained from the central fovea of the intact rhesus monkey retina with a technique adapted from Baron and Boynton[15]. A microelectrode, protected by a guide needle, was driven through the sclera and directed to the macular region under direct observation. The tip of the electrode (~1 μm) was positioned in the outer segment layer of the central fovea and a reference electrode was placed in the vitreous at 1 mm from the retina. The responses are averages of 90 flashes, each lasting 300 ms; repetition time was 1,200 ms. Vertical calibration bars represent 50 μV. The left-hand panels show responses to 447-nm and 551-nm flashes presented on a 10^5 troland yellow/orange background (Schott OG 570 cut-off filter). Stimulus intensities were 3.2 log td and 4 log td, respectively. Both waveforms have a distinct b-wave. The right-hand panels show responses to exactly the same stimuli, 1 s after extinction of the background. At 447 nm, top right, the b-wave has disappeared, whereas at 551 nm, bottom right, the whole response has increased in amplitude (note the smaller calibration bar). For the purpose of response averaging in the 'after yellow' condition, the background was repeatedly turned on and off, the on-phase lasting 10 s, the off-phase 1.6 s. In each dark interval one 300-ms flash was given 1 s after extinction of the background. This cycle was repeated until 90 responses were averaged. The extinction of a 10^5 troland yellow background field produces a large off-response that contaminates the recordings in the 'after yellow' condition. Therefore, this off-response was recorded separately, averaged, stored and subtracted from each averaged response in the 'after yellow' condition. Both stimulus and background field subtended 10°, centred around the fovea. The receptive field of our microelectrode is about 8°. Responses from stray light beyond the 10° stimulus field therefore do not contribute to the signal.

in the 'during yellow' condition and this is usually called chromatic adaptation. Turning off the yellow/orange background leaves the blue cone sensitivity unaltered (see the 'after yellow' data points), but the long-wave sensitivity increases by about 1.6 log units which is as expected after removal of a yellow/orange chromatic adapting field. Figure 2*b* shows the b-wave spectral sensitivity data. The 'during yellow' data at short wavelengths are again fitted with the macaque blue cone spectral sensitivity function[7], but the long- and middle-wavelength points are now fitted with the green cone spectral sensitivity function[9] (this will be discussed below). In the 'after yellow' condition the sensitivity at short wavelengths is about 1.5 log units lower than in the 'during yellow' condition, which is indeed transient tritanopia: shortly after extinction of a yellow/orange background there is a marked decrease in sensitivity for blue stimuli[10]. The middle- and long-wave sensitivity increases by about 1 log unit when the background is removed.

To determine which cone mechanisms mediate the b-wave spectral sensitivity 'after yellow', we tried to fit the $V_{10,\lambda}$ function and the blue cone spectral sensitivity function to the data. However, a good fit could not be obtained. Apparently, the blue cone system does not contribute to the response. The green cone spectral sensitivity function[9], however, gives a very satisfactory fit between 400 and 620 nm. The sensitivity at 660 nm is clearly higher than predicted by the green cone sensitivity curve but this is probably caused by a contribution of the red cone system to the response. These findings corroborate the psychophysical results of Mollon and Polden[2], who describe the short-wavelength spectral sensitivity (<500 nm) in the 'after yellow' condition using Stiles' π_4 (green sensitive) mechanism. It is indeed surprising that the green cone spectral sensitivity function, which certainly does not fit the receptor potential data, fits the b-wave data points 'during yellow' and 'after yellow' in the above mentioned spectral regions, and that the $V_{10,\lambda}$ function does not. This might be explained by previously reported colour-opponent features of the b-wave[11,12].

Pugh and Mollon[13] recently proposed a two-site adaptation model for Stiles' π_1 (blue sensitive) mechanism that includes an explanation of transient tritanopia. The first site is in the receptors themselves and the second site is believed to be in the retina proximal to the receptors. This second site is thought to have blue–yellow colour-opponent properties. It is supposed that sensitivity at the second site depends on the balance of the blue and yellow signals, being least when the site is polarised. To account for transient tritanopia it is suggested that a restoring force, which acts to reduce the polarisation of the site, is built up slowly during adaptation to the yellow field and continues to act for some time after extinction of the field, so producing a polarisation in the opposite sense. The present results fit this view rather well: the operational inhibition of the blue cone signal does not take place at the receptor level, but at some more proximal site. As the suppression is manifest at the level of the b-wave, it must take place at the bipolar cells[6] or earlier. The horizontal cells, which are distal to the bipolar cells, are the most likely candidates for blue cone inhibition: first, because of their anatomical suitability (they make cross-connections between various receptor cells) and second, because, at least in lower vertebrates, they are chromatically coded[14].

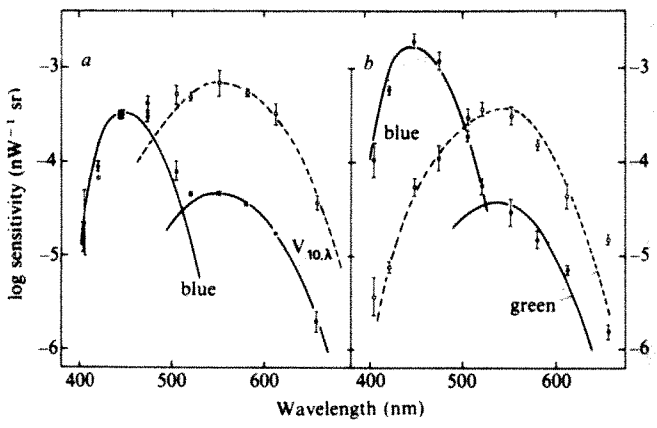

Fig. 2 *a*, Spectral sensitivity of the receptor activity, measured on a yellow/orange background (●) and 1 s after extinction of this background (○). Data are averages of three experiments. Receptor activity, the LRP or proximal PIII, was estimated by measuring the slope of the leading edge of the LERG response. Taking the initial slope allows consideration mainly of distal PIII without contamination of subsequent proximal PIII, onset of the b-wave potential or feedback from higher order cells[16]. Criterion for sensitivity was a response of 2 μV ms^{-1}. Error bars represent ±1 s.e.m. *b*, Spectral sensitivity of the b-wave 'during yellow' (●) and 'after yellow' (○). The b-wave amplitude was defined as the distance between initial positive peak and first negative deflection. Criterion was 45 μV and error bars represent ±1 s.e.m. This figure shows transient tritanopia: the sensitivity for blue (short wave) stimuli is much reduced when the yellow/orange background is removed ('after yellow' data points), compared with when the background is present. This is in contrast to *a*, where the blue sensitivity 'during yellow' and 'after yellow' is the same.

In conclusion, our electrophysiological data confirm the hypotheses based on psychophysical studies[2,3] in two ways: short-wavelength flashes, after switching off a yellow adaptation light, are 'seen' by the green cones rather than by the blue cones; and the inhibition of the blue cones can probably be located at the horizontal cell level.

Rapid effect of change in cerebrospinal fluid sodium concentration on salt appetite

THIRST can be evoked within 1–2 min by intracarotid infusion of hypertonic NaCl. In contrast, the onset of a specific appetite for sodium salts as a result of rapid loss of body sodium is slow. A parotid fistula in naive sheep can produce a significant Na deficit (200–700 mmol) within 1–3 d but a Na appetite usually develops after 2–5 d (ref. 1). With large urinary water and Na loss induced by frusemide, water intake occurs within an hour but Na appetite is delayed until 24 h (ref. 2). Moreover, in the Na-depleted sheep or goats, increase in the Na concentration of cerebral arterial blood by 10–30 mmol l^{-1} by slow intracarotid infusion of 4 M NaCl for 7 min before or during presentation of Na solution does not reduce Na intake[3,4]. However, rapid intravenous infusion of significant amounts of isotonic and 2–4 M NaCl solutions in Na-deficient sheep substantially reduces Na appetite after 40–120 min[5,6]. In the rat, tissue fluid sequestration produced by subcutaneous polyethylene glycol injection causes water drinking within an hour, but onset of salt appetite is delayed by 6–10 h.[7] This delay also occurs in salt appetite produced by peritoneal dialysis[8], tourniquet release[9] and formalin injection[10,11]. New data indicate the powerful effects of the hormones involved in the reproductive process in inducing salt appetite. With pregnancy and lactation in Na-replete rabbits, avid salt appetite develops with a daily turnover of 50% or more of extracellular fluid (ECF) Na (ref. 12). This is caused by the combined action of oestradiol, cortisol, ACTH, prolactin and oxytocin[13]. ACTH seems to act directly on the brain[14]. Recent experimental data provide new information on the central nervous system control mechanism. Weisinger *et al.*[15] reported that in Na-depleted sheep, the systemic influx of hypertonic NaCl significantly reduced motivation for salt within 10–20 min. In the light of these data, we decided to evaluate the effect on Na appetite of increasing the cerebrospinal fluid (CSF) Na concentration or osmolality in Na-deficient sheep. We now report the first experiments to show that it is feasible to induce salt appetite within an hour or less by a physiological procedure.

Sheep with a parotid fistula were trained to bar press for 600 mM $NaHCO_3$ (15 ml per delivery = 9 mmol Na). They were allowed to bar press for 2 h daily (1200–1400 h), and thus had been deprived of Na for 22 h (deficit of 350–450 mmol) when the bar press was made available. On the day of the experiment, the infusion (1 ml h^{-1}) into a lateral brain ventricle was begun 1 h before and continued until the end of the 2-h bar press period. The composition of artificial CSF has been described previously[16,17]. CSF was sampled immediately after the end of infusion and analysed for [Na], [K] and osmolality. Data were analysed by a two-way analysis of variance with subsequent *t*-tests.

The results (Fig. 1, $n = 6$) show that within 10 min, intraventricular infusion of CSF [Na, 500 mM] caused a significant decrease in Na intake relative to infusion of CSF [Na, 150 mM]. When an infusion of 0.7 M mannitol–CSF[Na, 150 mM] was used to test the effect of increasing CSF osmolality without increasing CSF [Na], Na intake was almost doubled (Fig. 1). The increase relative to the CSF [Na, 150 mM] infusion was significant within 60 min and thereafter. In experiments where no i.v.t. infusion was given, the intake was similar to that with CSF [Na, 150 mM]. In five animals tested Na appetite was significantly increased within 60 min whether the mannitol infusion was begun 60, 15 or 0 min before the bar press period. No significant increase in water intake occurred. The effect of mannitol infusion on Na intake was the same whether water was concomitantly available to the animal or not.

Relative to infusion of CSF[Na, 150 mM], CSF (Na, 500 mM) increased CSF [Na] and therefore osmolality and decreased CSF [K]. Infusion of 0.7 M mannitol–CSF[Na, 150 mM] decreased CSF [Na] and [K], and increased CSF osmolality (Table 1).

The question of whether hypertonic mannitol would induce a Na appetite in Na-replete sheep was then examined. Naive Na-replete sheep with no known history of Na deficiency were given continuous access to water. Two-hour access to a bin containing 600 mM $NaHCO_3$ was given daily for a control period of 2–4 weeks. After two or three control infusions of artificial CSF[Na, 150 mM], which had no significant influence on $NaHCO_3$ intake (Fig. 2), the animals ($n = 5$) were infused on three consecutive occasions with 0.7 M mannitol–CSF[Na, 150 mM] (Fig. 2). This was usually done on three consecutive weeks. A 3-h infusion (1 ml h^{-1}) into a lateral brain ventricle was begun 1 h before access to Na.

Na intake increased in all animals on each of the three mannitol–CSF infusion days relative to the mean Na intake on the two days preceding the infusion ($P < 0.01$) in all experiments (Fig. 2). The following day intake was basal or below. A small increase in water intake occurred during the first hour of infusion on trial 3 ($P < 0.02$) but was never increased during the 2-h period when $NaHCO_3$ was available. In 18 other experiments with a cafeteria of Na, K and Mg salts the specificity of choice of Na salts was clearly shown (300–500 mmol increase,

Table 1 Effect of a 3-h i.v.t. infusion of various solutions on CSF composition

Condition	Na (mM)	K (mM)	Osmolality (Mosmol)
CSF[Na, 150 mM]	151.2 ± 0.4 (25)	2.84 ± 0.03 (25)	297 ± 1.3 (15)
0.7 M Mannitol CSF[Na, 150 mM]	129.9 ± 1.4‡ (28)	2.52 ± 0.02‡ (28)	379 ± 7.8‡ (17)
0.3 M Mannitol CSF[Na, 0 mM]	127.0 ± 2.8‡ (5)	2.72 ± 0.11 (5)	319 ± 7.2‡ (5)

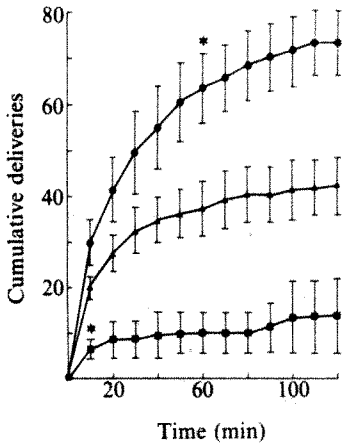

Fig. 1 Effect of i.v.t. (lateral ventricular) infusions on bar pressing for $NaHCO_3$ solution. The sheep were Na depleted as a result of parotid salivary loss for 22 h. Cumulative mean (±s.e.m.) number of deliveries (15 ml 0.6 M $NaHCO_3$ = 9 mmol) over the 120-min period in the various conditions: ■, 3 h i.v.t. infusion (1 ml hr^{-1}) of artificial CSF [Na, 500 mM]; ▲, artificial CSF[Na, 150 mM]; ●, 0.7 M mannitol–artificial CSF[Na, 150 mM]. Infusion was started 1 h before the bar press period. $n = 6$ Na-deficient sheep. *Significantly different from CSF[Na, 150 mM] values, $P < 0.05$.

$P < 0.01$), although a small increase in $KHCO_3$ sometimes occurred.

With i.v.t. hypertonic mannitol the decrease in CSF [Na] and [K] was presumably due primarily to the osmotic withdrawal of water from the choroid plexus and surrounding brain tissue capillaries. A decrease of CSF [Na] with less water movement was obtained by infusion of 0.3 M mannitol–CSF[Na, 0 mM] ($n = 7$) (Table 1). The Na appetite induced was similar to that with 0.7 M mannitol–CSF[Na, 150 mM] (Fig. 2). No increase in water intake occurred.

The results of these experiments indicate that a change in the composition of CSF involving an increase or decrease in [Na] may rapidly alter salt appetite drive. A rapid induction, within 60 min or less, of a large Na appetite has been shown.

The induction of a Na appetite in the naive Na-replete sheep, augmentation in the moderately deplete animal, the demonstration by both voluntary intake and operant behaviour and the inhibition of appetite as a result of increase of CSF [Na] in the Na-deficient animal strengthen the inference that altered CSF [Na] affected the physiological control system. In all cases, the

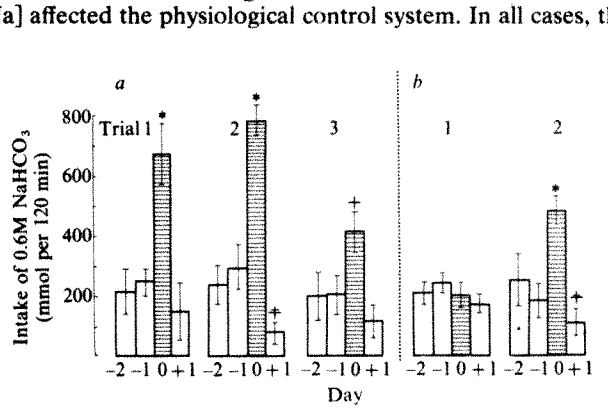

Fig. 2 *a*, Effect of 3 h i.v.t. infusion (1 ml h^{-1}) of 0.7 M mannitol–artificial CSF[Na, 150 mM] on voluntary intake of 0.6 M $NaHCO_3$ by 5 Na-replete sheep. Infusion was started 1 h before the 2 h access period on day 0. No infusion on days −2, −1 or +1. Water was continuously available. The effect of infusion on Na intake on three trials on consecutive weeks is shown. *b*, Effect in the same conditions of infusion of artificial CSF[Na, 150 mM] (1), 23 experiments in 13 sheep, and 0.3 M mannitol–artificial CSF[Na, 0] (2), 7 sheep. *$P < 0.001$; †< 0.01; ‡$P < 0.02$.

experimentally induced changes in CSF [Na] were in the physiological range. The absence of significant water drinking despite an increased osmotic pressure may be due to concurrent decrease of CSF [Na][17,18]. With i.v.t. CSF [Na, 500 mM] infusions, if water was available during the whole infusion, or in the period 0–120 min when Na HCO_3 was available, drinking of 1–2 l occurred.

The results are consonant with the suggestion by D.A.D. that reduction in intracellular [Na] of the hypothalamic nerve cells subserving Na appetite is the basic mechanism for the genesis of this specific drive[19]; however, further experiments are required to confirm this. Whether the time interval for CSF changes to induce behaviour is too short for a transcription mechanism is also a matter for further investigation. Intracellular ionic change could act at the level of translation[20]. A change in brain ECF [Na] may also have a direct effect on the membrane. The fact that the large salt appetite in the Na-replete animal during reproduction is generated by a sequence of steroid and peptide hormone actions[21], presumably by the same neural mechanisms which respond to body Na deficit, is consistent with the idea that a complex neurochemical mechanism underlies the genesis of salt appetite.

Immunisation of guinea pigs and cattle against ticks

IXODID TICKS attach to the skin of their host and remain there for several days, engorging on blood and intermittently passing salivary secretions into the host[1]. Several species of Ixodid ticks transmit pathogenic microorganisms along with their saliva into the host, and tick-borne diseases are of great economic importance, particularly in cattle in subtropical and tropical areas[2]. The control of cattle ticks by chemical acaricides has become increasingly difficult due to the emergence of acaricide-resistant strains of ticks[3]. An apparently novel immunological method of tick control in guinea pigs and cattle is reported here. Hosts were immunised with antigens extracted from the gut and

* Each guinea pig was infested with four male and four female ticks.
† Antigen preparations: midgut, reproductive and other organs were dissected from female ticks which had fed for 5 d on guinea pigs. Dissected organs were held in ice-cold phosphate buffered saline (*p*H 7.2, 0.01 M in 0.15 M NaCl). Antigen I was extracted from midgut and reproductive organs, antigen II from all internal organs. Tissues were homogenised, centrifuged at 10,000*g* for 30 min, and the supernatants held at 4 °C. Protein concentrations were estimated by the Lowry method[12].

other internal organs of partially fed ticks. Ticks which subsequently parasitised these hosts showed significantly reduced feeding and reproductive performance. These experimental results raise the theoretical possibility of controlling some species of cattle ticks by appropriate immunisation of their hosts.

It has been known for some time that guinea pigs acquire a resistance to tick feeding[4]. For example, they allow approximately 80% of *Dermacentor andersoni* larvae to engorge during a primary 5-d infestation of one ear, but <10% of the larvae engorge during a subsequent similar infestation of the opposite ear. Such acquired tick resistance is an immunological phenomenon, abrogated by the use of immunosuppressants, and transferable between syngeneic guinea pigs with viable lymph node cells. Tick resistance is accompanied by a cutaneous hypersensitivity to antigens derived from the salivary glands of the tick, and a degree of resistance has been induced artificially in guinea pigs using such antigens[5–7].

Cattle may also acquire a similar resistance to the tropical cattle tick *Boophilus microplus*, following a series of infestations. However, the ability to acquire high level resistance to the tick is confined to certain strains of cattle. This ability is more often evident in *Bos indicus* than in *Bos taurus*, but the ability varies markedly from animal to animal within and between breeds[8–11]. At present, the causes of this variability are not known, and artificial induction of high level tick resistance has not been achieved in cattle by use of tick salivary gland antigens.

Immunisation trials reported here used antigens from the ticks' midgut and reproductive organs, and were based on the crude concept that ticks feeding on appropriately immunised hosts might ingest antibodies specific for antigens within the alimentary tract and reproductive organs of the tick, producing deleterious effects on the feeding and reproductive behaviour of the tick.

Antigenic extracts were prepared from female *D. andersoni* ticks which had been allowed to feed for 5 d on outbred guinea pigs. Extracts from tissues of unfed ticks had previously been found to be ineffective. Midgut, reproductive and other organs were dissected from the ticks. Two antigenic extracts were prepared; antigen I from the midgut and reproductive organs, and antigen II from all internal organs of the tick.

Eighteen outbred guinea pigs, weighing 400–450 g, were randomly placed in three groups. Animals in group I received antigen I 1.2 mg per kg body weight in Freund's complete adjuvant (FCA) on days 0 and 14. Animals in group II were immunised with similar doses of antigen II in FCA. Control animals (group III) received similar injections, lacking tick antigens, at the same time. All injections were given intradermally into footpads. On day 28, each guinea pig was infested with four male and four female *D. andersoni*. Ticks were removed from the guinea pigs 2 weeks later. The ticks were weighed, and females were placed individually in vials held at 24 °C in a relative humidity of 85%. The egg mass produced by each female was weighed, and the numbers of larvae hatching within 35 d of removing the ticks from their hosts were recorded.

The results of this experiment are shown in Table 1. Ticks engorged on four of the six control guinea pigs and produced egg masses from which large numbers of larvae hatched. Ticks feeding on animals immunised with antigen I produced relatively few eggs from which no larvae hatched. Those placed on guinea pigs immunised with antigen II neither engorged nor laid

* Each calf was infested with 30 male and 100 female *D. andersoni*, confined to the ears within double cotton bags.
† Antigen I was prepared as before, from female ticks which had fed on cattle. Protein concentrations of the extracts were estimated by the Lowry method[12]. Antigen preparations were held at 4 °C until used.
‡ Differences in the performances of ticks on immunised and control calves were analysed by Student's *t* test.

eggs. The success in using antigenic extracts of partially fed ticks, in contrast to previous failure with extracts of unfed ticks, may reflect the developmental and presumably antigenic changes which occur in the midgut epithelium and other tissues of the feeding female Ixodid tick[1]. These results were considered to be sufficiently encouraging to undertake a pilot experiment with *D. andersoni* infestations of immunised and control cattle.

Antigen I was prepared, as before, from female *D. andersoni* which had fed for 5 d on the ears of Holstein steers. Eight Hereford-cross calves, which had not previously met ticks, and which weighed between 180 and 280 lb, were randomly divided into test and control groups. Each calf to be immunised received 67 mg antigen in Freund's incomplete adjuvant on days 0 and 16. A similar dose without adjuvant was administered on day 25. All injections were given by the intramuscular route. Control calves received similar injections, lacking the tick antigens, on the same days. All calves received 10-d tick infestations starting on day 28. Measurements of the ticks' feeding and reproductive performances were recorded as shown in Table 2. Serum samples were obtained from all calves on days 0, 16, 25, 28 and 38. Immunodiffusion tests were run with these samples and the immunising antigen.

From the results shown in Table 2, it is evident that there was no significant difference in the total numbers of ticks recovered from immunised and control calves. Significantly lower total weights of live ticks, lower egg production and fewer larvae were found in infestations of immunised compared with control calves. No larvae were produced by ticks which infested immunised calf number 2.

Immunodiffusion studies revealed single precipitation bands between the immunising antigen and sera collected on days 16, 25 and 28 from all immunised calves. Strong multiple bands were obtained with sera collected from calves 1, 2 and 7 on day 38, but single bands only were obtained from the serum collected from calf 8 on that day. This calf was the youngest of the group and produced the least impressive results on tick challenge.

It seems that the feeding and reproductive performances of ticks infesting immunised calves were significantly reduced. It seems reasonable to speculate that more impressive results may be obtained in cattle immunised with antigen II. Such immunisations are now being investigated. Theoretically, such an immunological method of tick control might be expected to be most effective against such species as *Boophilus microplus*, a relatively host-specific cattle tick, the larvae, nymphs and adults of which must feed in sequence from the same host. There would be potential problems in purification and large scale production of antigens but, if all cattle in an area could be successfully immunised, one might expect significant reduction in both numbers of ticks and in the tick-borne diseases of cattle.

This investigation was supported in part by a grant from the Merck Institute for Therapeutic Research, Rahway, New Jersey.

Involvement of a gene on chromosome 9 in human fibroblast interferon production

HUMAN fibroblast interferon is a single monomeric glycoprotein[1], and presumably a single structural gene codes for the human interferon polypeptide. It was originally reported that chromosomes 2 and 5 were necessary together for human interferon production[2]. More recent evidence suggests that both chromosomes 2 and 5 carry separate human interferon genes[3,4]. However, we have found, in two separate series of human–mouse somatic cell hybrid cell lines and their diphtheria toxin-resistant subclones[5,6], that human interferon production segregated from chromosome 5 and, furthermore, did not correlate with the presence of chromosomes 2 and 5 together[7]. Furthermore, using 29 hybrid clones (13 independent primary hybrids and 16 subclones) we could exclude chromosomes 1–8, 10–22 and X as candidates for the localisation of a single gene coding for human interferon on the basis of discordance of more than three clones for the segregation of human interferon production and the presence of a particular chromosome. However, there was a good correlation between the production of human interferon and the presence of chromosome 9. Here we demonstrate this directly.

The human fibroblast cell line, GM705 (Human Genetic Mutant Cell Repository, Camden, New Jersey) contains one normal inactive X chromosome and an X; 9 translocation (q12; p24) in which the long arm of X carrying the genes coding for hypoxanthine–quanine phosphoribosyl transferase (HPRT) and glucose-6-phosphate dehydrogenase (G6PD) is translocated onto chromosome 9 (refs 8, 9). When these cells are fused with mouse cells lacking HPRT, the X; 9 translocated chromosome bearing the gene for human HPRT can be selected for using the standard hypoxanthine–aminopterin–thymidine (HAT) selection procedure and selected against by 8-azaguanine. Thus, we used hybrid cells containing the X; 9 translocated chromosome to test directly the involvement of chromosome 9 in human interferon production.

Human GM705 cells, grown in Ham's F12 medium plus 20% fetal bovine serum (FBS) were fused with the $HPRT^-$ mouse cell lines L-A9 (ref. 10) and PG19 (ref. 11) using polyethylene glycol (molecular weight 6,000 (ref. 12)). Hybrid cells were selected in Ham's F12 plus 10% FBS containing HAT (hypoxanthine 13.6 $\mu g\,ml^{-1}$, aminopterin 0.19 $\mu g\,ml^{-1}$, and thymidine 3.9 $\mu g\,ml^{-1}$) and ouabain (10^{-5} M)[13], which kill mouse and human parental cells, respectively. Hybrid cell lines were isolated as previously described[7], grown to confluency in 100-mm plastic dishes ($1.5–4.0 \times 10^6$ cells per dish) and induced for interferon production with Newcastle disease virus (NDV) strain F (1×10^{-4} haemagglutinating units per cell). Interferon containing fluids were collected at 20–24 h post infection, dialysed for 5 d at 4 °C against *p*H 2 buffer to inactivate residual NDV and returned to *p*H 7.4 by dialysis against culture medium. They were then assayed for human and mouse interferon in human embryo or foreskin fibroblasts and mouse L-A9 or L-929, respectively, using the method of 50% inhibition of viral ribonucleic acid synthesis ($INAS_{50}$)[14]. Neither human nor mouse interferon gave a detectable antiviral response in the respective heterologous cell system. Use of specific antisera showed that the hybrids produced human fibroblast interferon and not human leukocyte interferon.

Eight independently selected hybrid cell lines formed from the fusion of human GM705 and mouse PG19 all produced human and mouse interferons, although titres of human interferon produced were substantially less than those of mouse interferon (Table 1). GM705 fibroblasts produced 10^2 U per ml per 10^6 cells when virally induced in the same conditions. Isozyme analyses of GP hybrids indicates that all eight contain enzyme markers for chromosomes X and 9 (that is, G6PD, AK1, AK3 and $ACON_s$, see Table 1 legend for abbreviations) and in

Metaphase chromosomes were banded and stained using the method of Bishun *et al.*[15]. Twenty-five metaphase figures were analysed for each hybrid cell line and numbers of human chromosomes expressed as percent. Human isozymes used as markers for individual chromosomes were, with the exception of *N*-acetyl hexosaminidase-β, tested by routine electrophoretic methods (Harris and Hopkinson[16,17]). *N*-acetyl hexosaminidase-β was assessed by immunodiffusion (Swallow *et al.*[6]). Abbreviations: ENO_1, enolase-1; PEPC, peptidase-C; MDH_S, soluble malate dehydrogenase, ACP_1, acid phosphatase-1; ICD_S, soluble NADP-dependent isocitrate dehydrogenase; HEX_β, *N*-acetyl hexosaminidase-β; ME_S, soluble malic enzyme; AK_1, adenylate kinase-1; AK_3, adenylate kinase-3; $ACON_S$, soluble aconitase; GOT_S, soluble glutamate-oxaloacetate transaminase; LDH_A, lactate dehydrogenase-A; PEPB, peptidase-B; ESD, esterase-D; NP, purine nucleoside phosphorylase; MPI, mannose phosphate isomerase; APRT, adenine phosphoribosyl transferase; GALK, galactokinase; PEPA, peptidase-A; GPI, glucose phosphate isomerase; ADA, adenosine deaminase; SOD_A, superoxide dismutase; $ACON_M$, mitochondrial aconitase; G6PD, glucose-6-phosphate dehydrogenase. I, isozyme analysis; C, chromosome analysis; ND, not done.

* Titres expressed as reference research units per ml per 10^6 cells.

† The normal inactive X chromosome was lost in GL-C, presumably due to the 'random' segregation of this chromosome.

addition have several other human chromosomes in common. The chromosome 5 marker HEX_β was absent or present only in trace amounts (Table 1). The three chromosome 2 enzyme markers tested (MDH_S, ACP_1, ICD_S) were also absent in one clone (GP-2). This particular clone (GP-2) also responds to polyriboinosinic acid: polyribocytidylic acid and superinduction and has retained the capacity to produce human interferon when virally induced after 6 months in continuous serial culture in medium containing HAT.

Further hybrids were prepared from the fusion of GM705 and mouse L-A9 cells. One of these, GL-A, contained chromosome 5, was selected with diphtheria toxin at 10^{-1} L_f ml^{-1} (see ref. 5) in the presence of HAT, and the resulting resistant (segregant) cells grown and tested for interferon production. These derived cells, GL-B, maintained the ability to produce human interferon at the same level as the parental hybrid, GL-A (Table 1). However, when GL-B cells were exposed to 8-azaguanine (10 μg ml^{-1}) to select against the X; 9 chromosome, and resistant hybrid cells (GL-C) grown and tested for interferon production, the capacity to produce human interferon was lost (Table 1). Recently, similar results have been obtained after growth of GP-2 in 8-azaguanine. Karyotype and isozyme analyses of GL-A, B and C (Table 1) showed that chromosome 5 was eliminated by diphtheria toxin (GL-B) and X; 9T by 8-azaguanine (GL-C).

The production of high levels of human interferon by all the clones selected to contain the X; 9 chromosome, and the loss of human interferon production in the 8-azaguanine-resistant clones strongly suggest that a gene on the X; 9 chromosome is involved in human interferon production; this is presumably on 9 rather than on X, as previously we have found 11 clones discordant for the presence of X and human interferon production[7]. The only other chromosomes lost in GL-C that were present in GL-B were chromosome 12, which has been excluded in our previous study[7], and the inactive X chromosome.

Thus, our data point to the assignment of the human fibroblast interferon gene to chromosome 9 rather than 2 or 5, as these are absent in one or more of our hybrid clones which are inducible for human interferon. As fibroblast interferon is a glycoprotein, the products of genes other than the structural gene must be required for the secondary modification of the human interferon polypeptide. This modification may be completed by products of the rodent genome. However, we cannot exclude the possibility that genes on the other human chromosomes in addition to chromosome 9 are required for human interferon production in our hybrids, but neither 2 nor 5 seem to be involved. The basis for the discrepancy of our results from those of Tan[3] and Slate and Ruddle[4] is not clear. These authors did not observe chromosome 9 in any of their reported hybrids[2,4]. However, Slate and Ruddle (persbnal communication) have now also shown that chromosome 9 does contain a structural gene for human interferon by using a human–mouse hybrid containing chromosome X; 9 as the only human chromosome. C. Chany (personal communication) also has evidence for the involvement of chromosomes 2, 5 and 9. Thus, it is possible that there is more than one structural gene for human interferon, and that they are on different chromosomes, although our evidence so far fails to show this.

We thank the MRC for a programme grant enabling us to carry out this research, and Lorraine Evans and Steve Jeremiah for technical assistance. Diphtheria toxin was from Dr D. C. Edwards (Wellcome).

Sheep fetal haematopoietic cells produce adult haemoglobin when transplanted in the adult animal

DURING the fetal stage of development, the human erythroid cells synthesise mainly fetal haemoglobin ($\alpha_2\gamma_2$) but switch to almost exclusive formation of adult haemoglobin ($\alpha_2\beta_2$) soon after birth. Similar ontogenetic changes in the activity of the closely linked γ- and β-genes are seen in most primates and few other mammals. In goats and sheep over 95% of the haemoglobin synthesised in the fetus is of the fetal type; the switch from fetal to adult haemoglobin formation starts at about 130 gestational days and is completed within a few weeks[1]. Several hypotheses have been formulated to account for these striking changes in haemoglobin gene activity during ontogeny, but the factors responsible for haemoglobin switching *in vivo* remain unknown. We report here an experiment which shows that the fetal haematopoietic cells readily switch to adult haemoglobin formation once transplanted to an adult animal. Our findings provide evidence that the switch from fetal to adult haemoglobin formation is not restricted to the perinatal developmental stage, and raise the possibility that the haematopoietic microenvironment determines the programme of haemoglobin formation in the haematopoietic progenitor cells of the fetus or the adult animal.

The experiment involved transplantation of haematopoietic cells from sheep fetuses aged 100 gestational days to adult female sheep. To have definitive markers of a successful graft of the transplanted tissue and to distinguish between the globin produced by the donor and the recipient red cells, we used the polymorphism at the β-haemoglobin locus of the sheep[2]. There are two common alleles of this locus, β^A and β^B, directing the synthesis of the two sheep haemoglobins A($\alpha_2\beta_2^A$) and B($\alpha_2\beta_2^B$). The two haemoglobins can be clearly separated and quantitated by isoelectric focusing[3]. We therefore transplanted fetal haematopoietic cells known to be homozygous for the Hb *A* gene to recipient adult animals who were homozygous for the Hb *B* gene.

The fetal haematopoietic cells were obtained from the livers and bone marrow of twin sheep fetuses. No matching between donor and recipient cells was done. The cells (10^7 cells per kg body weight) were infused in the donor animal, which had been lethally irradiated (950 rads per total body) 2 h before the cell infusion. One of the irradiated animals died 1 d after transplantation; two other animals died at post-transplant days 11 and 15. The fourth Hb *BB* animal was transplanted with cells from a closely related Hb *AA* fetus (coefficiency of kinship 0.725), received post-transplant support with leukocyte transfusions (the leukocytes were obtained from a donor sheep that was homozygous for Hb *B*) and survived for 45 d; cause of death was an infection due to defective cannulation.

In this fourth animal, sequential haemoglobin analyses were carried out and findings are shown in Fig. 1. It is apparent that (1) there was a successful graft of the donor pluripotent stem cells, as Hb *A* appeared in the circulation of the Hb *BB* recipient; (2) the haematopoietic cells of the 100-d-old fetal donor switched to almost exclusive adult haemoglobin formation once they started supporting the erythropoiesis of the adult animal. There was no detectable production of Hb *C* by the transplanted *AA* cells. The small amounts of the fetal haemoglobin synthesised by the transplanted animal (Fig. 1*a*) were not unexpected as experiments in humans have shown that a transient production Hb *F* characteristically appears in post-transplantation erythropoiesis[4]. A control experiment of homotransplantation in a *BB* homozygous sheep showed that in the adult sheep, as in humans, post-transplantation erythropoiesis is associated with a transient increase in fetal haemoglobin production (Fig. 1*b*).

In vivo studies in man have clarified certain aspects of the cellular regulation of fetal haemoglobin production. Studies in patients with clonal haematopoietic stem cell disorders suggest that a single pluripotent stem cell can provide erythroid progeny which produce fetal haemoglobin as well as progeny which produce adult haemoglobin[5]. The interpretation of this is that the regulatory events that determine Hb *F* or Hb *A* production in the adult take place in haematopoietic cells that have left the

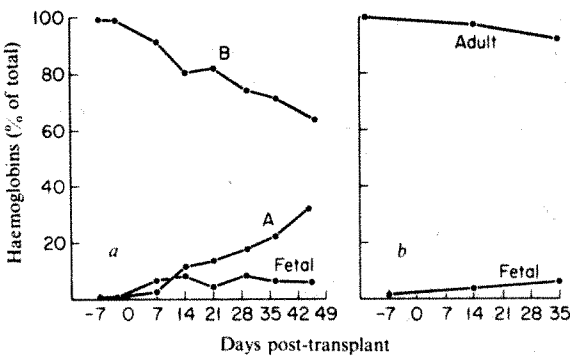

Fig. 1 Time course of haemoglobins A, B and F formation in sheep transplantation experiments. *a* Findings in a *BB* sheep transplanted with *AA* fetal sheep cells. *b*, The results of a homotransplantation experiment in a *BB* sheep; in *b* bone marrow cells were removed by multiple aspirations, the animal received 970 rads of whole body irradiation and was transfused with its own bone marrow cells. Note the appearance of a small amount of Hb *F* in the homotransplanted animal. The amount of Hb *F* is equivalent to that observed in experiment *a*.

pluripotent compartment of haematopoiesis. Evidence against the possibility that the pluripotent stem cells are irreversibly programmed for either fetal or adult haemoglobin expression is provided by the transplantation experiment described here. The transplanted stem cells were from a fetus which synthesised exclusively Hb *F*. If the Hb *F* phenotype of the red cell was determined at the pluripotent stem cell level, large amounts of fetal haemoglobin should have appeared in the circulation of the transplant recipient; instead, adult haemoglobin of the donor cell genotype (Hb *A*) appeared in the circulation as soon as there was evidence for engraftment of the transplant. Considering the size of the blood volume of the recipient and the volume of the transplanted cells, the best interpretation of the finding is that the erythroid progeny of the transplanted haematopoietic stem cells readily switched to adult haemoglobin formation.

This experiment is also informative with regard to the factors which are involved in the regulation of fetal to adult haemoglobin switching. Thus, the findings show that it is unlikely that the

© Macmillan Journals Ltd 1979

temporary presence of a regulatory substance during the perinatal period of ontogeny mediates the switching from fetal to adult haemoglobin formation. It is more likely that the fetal cells were switched to adult haemoglobin formation either because they were pre-programmed to switch at a given developmental time (130–140 d from conception) or because they were re-programmed to form adult haemoglobin when they were found in the adult environment. Of the two possibilities, we consider the first one less probable. Between 100 and 135 gestational days, the cells in the sheep fetus produce predominantly Hb *F* (refs 1, 6); if the transplanted stem cells continued to express a pre-determined developmental programme, predominantly Hb *F* would have been formed during the first month of repopulation of the haematopoietic tissue of the recipient animal, but, as shown in Fig. 1*a* and *b*, the amount of Hb *F* in the transplanted animal was no more than that produced by the adult cells of the homotransplant control. This finding suggests that the fetal cells readily switched to an adult haemoglobin formation programme when they were moved to an adult haematopoietic environment, and raises the possibility that the change in haematopoietic environment underlays the Hb *F* to Hb *A* switching in the transplanted cells. We therefore proposed that it is the continuous presence of certain microenvironmental influences in the fetal and their absence in the adult haematopoietic tissue (or the reverse) which makes the erythroid progenitors express the fetal or the adult developmental programmes.

The phenomenon of haemoglobin switching has a twofold interest: (1) as a prototype for understanding the regulation of gene activity in development and differentiation; (2) as a therapeutic model for the treatment of sickle cell anaemia and homozygous β-thalassaemia. Patients with both these disorders could become virtually asymptomatic if it was possible to reverse the switch from Hb *F* to Hb *A* formation. If environmental factors mediate this switch, identification of these factors and their mode of the interaction with the progenitor cells may provide clues to the treatment of the β-chain haemoglobinopathies.

Evidence of continuous evolutionary change in structures mediating adherence of lymphocytes to specialised venules

MANY cell–cell interactions are similar in a wide variety of species; for instance, penetration of ova by spermatozoa, morphogenetic cell movements during embryogenesis, and specific cellular cooperation during the immune response in vertebrates. The operation of apparently identical functional interactions in diverse species, however, does not exclude the possibility that the cell surface receptors and ligands involved may have changed considerably during evolution. In fact, studies of the molecular evolution of certain enzymes and proteins present in numerous species have demonstrated that structural evolutionary change (that is, amino acid substitutions) may proceed even in the absence of observed functional modification[1]. For this reason, we suggest that the investigation of the degree of evolutionary change in structures mediating conserved cell–cell interactions requires determination of the degree to which the interaction is possible between cells from different species. The present study was designed to examine quantitatively the effect of progressive evolutionary divergence on interspecies cellular cooperation in a simple, highly conserved cell–cell interaction: the specific adherence of lymphocytes to specialised lymphocyte-binding high endothelial venules (HEV) in lymph nodes. Based on results of quantitative *in vivo* and *in vitro* assays, we report that the ability of lymphocytes from different vertebrate species to recognise specifically and bind to HEV in the mouse declines exponentially with increasing evolutionary separation of the lymphocyte donor from the mouse host. This suggests that, in spite of conservation of the functional interaction in all mammalian species examined[2], the cell-surface structures mediating lymphocyte adherence to HEV have been continuously and randomly altered during evolution.

As originally demonstrated by Gowans and Knight[3], lymphocytes bind to and migrate through the endothelium of post-capillary HEV in lymph nodes during their normal recirculation from blood to lymph. The adherence of lymphocytes to HEV is a highly specific cell–cell interaction: other cells in the blood do not bind to HEV, and lymphocytes do not normally bind to other vessel walls. We have combined short-term *in vivo* homing studies with two previously described *in vitro* methods[4,5] (modified in our laboratory for quantitative analysis[6,7]) to examine the relative ability of lymphocyte populations from several vertebrate species to adhere to HEV in the mouse.

Briefly, the three assay systems used were: (1) an *in vivo* autoradiographic study, comparing the number of radiolabelled lymphocytes localising in HEV 15 min after intravenous injection; (2) a frozen section assay[7] (modified from the method of Stamper and Woodruff[5]), comparing the binding of various lymphocyte populations to HEV in fresh frozen sections of mouse mesenteric node during incubation at 7 °C; and (3) a perfusion assay[6] (modified from Sedgley and Ford[4]), comparing the adherence of lymphocytes to HEV during single pass systemic vascular perfusion at 37 °C. In each system, a specific adherence index (SAI) was calculated relating the observed adherence (to mouse HEV) of sample lymphocytes to that of mouse lymphocytes.

The SAI of splenic lymphocyte populations from several vertebrate species are related directly to the evolutionary distance[8–10] separating the lymphocyte donor from the mouse host (Fig. 1a). Two conclusions can be drawn from these data. First, the *in vitro* and *in vivo* assay systems give similar results. Second, the ability of lymphocytes to adhere to host mouse HEV is inversely related to the evolutionary separation of donor and host, yet is still significantly conserved in the most divergent species tested. (It is remarkable that birds, which are separated

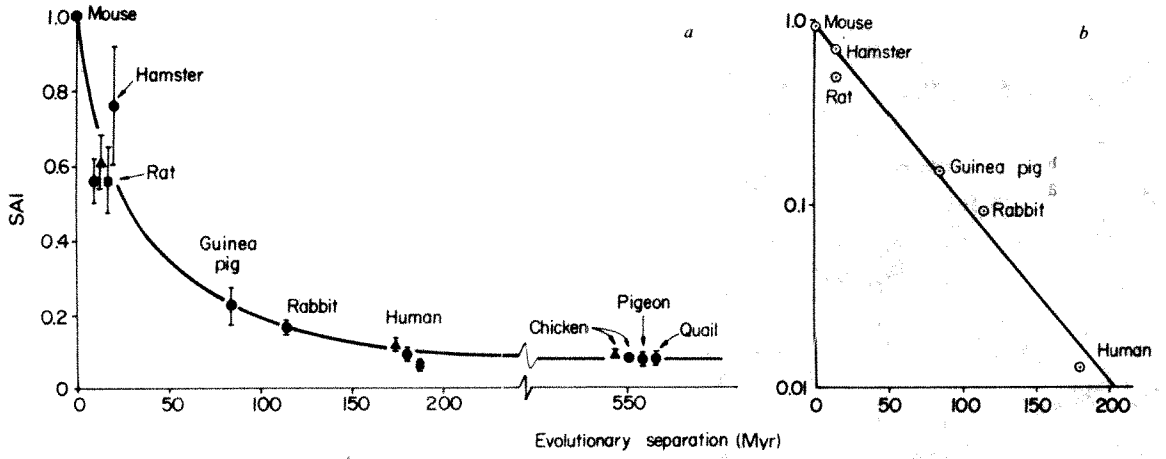

Fig. 1 *a*, Relationship between specific adherence index (SAI) and evolutionary separation of lymphocyte donor from mouse host. Adherence of sample lymphocytes to mouse lymphocyte-binding high endothelial venules (HEV) was measured *in vivo* 15 min after i.v. injection (▲); during single pass systemic vascular perfusion at 37 °C (■), or during incubation on frozen sections of mesenteric lymph nodes at 7 °C (●). The SAI of mouse lymphocytes is unity, and that of negative control cells is 0. Error bars are standard deviations of the ratio estimates. All samples were spleen cells except rat and mouse *in vivo*, which were pooled spleen and mesenteric node cells. 5–8-week-old (BALB/c × C57BL/6 Jax)F_1 mice, Lewis rats, Syrian Gold hamsters, a 6–8-week-old Hartley guinea pig, 6–10-week-old White Leghorn or New Hampshire Red hens, 6-week and 1-year old New Zealand White rabbits, and young adult quail and King pigeons were used. Human spleens were uninvolved laparotomy specimens from young patients with Hodgkins disease. *b*, Demonstration of negative exponential relationship after subtraction of the conserved baseline adherence fraction ($K = 0.080 \pm 0.008$) typified by avian lymphocyte adherence. Data from frozen section assay. *In vivo* system (▲): autoradiographs were made of sections of mesenteric lymph nodes taken from mice killed 15 min after i.v. injection of 10^8 ^{3}H-leucine or ^{3}H-uridine labelled donor lymphocytes. SAI is defined as the average number of sample lymphocytes per ×40 microscope field of lymph node paracortex (either in HEV or already inside the node) divided by the corresponding value for mouse lymphocytes. Background (non-adherent labelled lymphocytes passively trapped in HEV) was less than 3% of even the most poorly adhering sample population. Frozen section assay (●): a monolayer of lymphocytes in Hank's balanced salt solution containing 1% bovine serum albumin was incubated at 7 °C for 30–45 min on freshly cut unfixed frozen sections of mouse mesenteric node. Medium was removed and the section fixed with 1% glutaraldehyde in cold phosphate-buffered saline. After fixation, non-adherent cells were gently rinsed off. To allow quantitative comparisons, an internal standard population of fluorescent lymphocytes labelled by 15 min incubation with 60 μg ml^{-1} fluorescein isothiocyanate (FITC) at 37 °C or 5–50 μg ml^{-1} rhodamine isothiocyanate (RITC) at 25 °C, was mixed with each population before incubation. A reference sample of mouse lymphocytes and a negative control population of erythrocytes or formalin-fixed lymphocytes were included. Data from at least 5 mesenteric node sections were pooled for each sample. The ratio of sample to standard cells in the incubation mixtures (R_I) and adherent to HEV (R_{HEV}) was determined. A specific adherence ratio, R_{HEV}/R_I, was calculated for each sample (SAR_S), for mouse lymphocytes (SAR_M) and for negative control cells (SAR_N). SAI was defined as: $SAI = (SAR_S - SAR_N)/(SAR_M - SAR_N)$. Standard deviations of all ratios were calculated by the delta method. Perfusion assay (■): a mixture of 10^8 ^{3}H-leucine labelled sample spleen cells, 10^8 RITC-labelled standard cells, and 10^8 formalin-fixed FITC-labelled thymocytes (as an internal negative control) in 15 ml medium 199 containing 1% bovine serum albumin was perfused at 37 °C and 2-3 ml per min through the systemic vasculature of an anaesthetised mouse (in via a trocar inserted in the left ventricle, out via an incision in the right atrium). Non-adherent cells were flushed with 10 ml medium. Solitary sample, standard, and negative control cells in HEV were counted in autoradiographs of 6-μm frozen sections of mesenteric nodes from duplicate perfusions. SAI were calculated as for the frozen section assay.

from mice by over 500 million years of evolution and lack morphologically well-developed HEV of the mammalian type[2], nonetheless have lymphocytes capable of recognising and adhering to mouse HEV (Fig. 2).) This decline is not limited to spleen cell populations, as a similar evolutionary decrease in adherence to mouse HEV was observed for mesenteric node lymphocytes from several mammalian species. Furthermore, in all cases examined (mouse, rat, rabbit and chicken) adherence remained a specific property of lymphocyte populations normally capable of entering lymph nodes *in vivo*: immature, non-migrating lymphocytes bound poorly in relation to their mature counterparts[6].

As shown in Fig. 1*b*, the observed relationship between SAI and evolutionary distance approximates a negative exponential function with a decay rate of 2.5 ± 0.3% of the adherence index per million years. Such a clearly defined relationship requires explanation. Although the physical characteristics of cells, such as cell size, surface morphology, surface charge, membrane protein and carbohydrate content or membrane fluidity may well influence certain cellular interactions, it is difficult to invoke such nonspecific parameters in the present case. There is no correlation between lymphocyte size or surface morphology and adherence to HEV—human lymphocytes are larger and exhibit more surface microvilli than either mouse or chicken lymphocytes (when adherent to mouse HEV after vascular perfusion—E. B., van Ewijk, and I. W., unpublished). It is unlikely that either surface charge or carbohydrate content has a significant role, as adherence is unaffected by treatment of lymphocytes with neuraminidase[11,12]. Membrane fluidity is probably not a critical parameter, as it is undoubtedly reduced at 7 °C, a temperature at which lymphocytes bind well to HEV in frozen sections. A possible relationship between overall surface protein content and adherence canot be ruled out, as light trypsinisation of the lymphocyte surface markedly reduces binding[11,12]; it seems more likely, however, that trypsinisation destroys a specific binding protein. Fundamentally, it is difficult to construct a role for gross physical parameters, or a mechanism for their orderly alteration during evolution, that would result in the observed negative exponential relationship between adherence and evolutionary separation.

On the other hand, it is interesting to consider this negative exponential relationship in light of the previously cited studies of the molecular evolution of proteins. Dickerson[1] has reviewed data demonstrating that several proteins (such as cytochrome *c* and haemoglobin) have incorporated amino acid substitutions at characteristic and fairly constant rates during evolution, even though they have continued to serve the same function in diverging lineages. A linear rate of amino acid substitution implies an exponential rate of decline in the fraction of mutable amino acids a protein shares with its progenitor or with diverging proteins (ignoring the minor contribution of reverse mutations back to the original amino acid). Such an exponential decline in shared amino acids could explain a roughly parallel decline in interaction compatibility of the proteins in diverging species. We propose that the observed exponential decline in lymphocyte–HEV adherence compatibility may be the functional result of a linear rate of evolutionary mutation in the components—presumably amino acids—of the cell-surface structures mediating the interaction. Although natural selection would have ensured the continuing compatibility of 'drifting' lymphocyte and HEV surface receptors within a given species, no selective pressure would have prevented progressive development of incompatibility of interaction structures in diverging lineages. Strong selection against abrupt, major changes in the interactive sites of lymphocyte and endothelial cell receptors may have protected certain essential components from mutation, thus explaining the baseline level of interspecies compatibility demonstrated by avian lymphocytes (*K* in Fig. 1*b*).

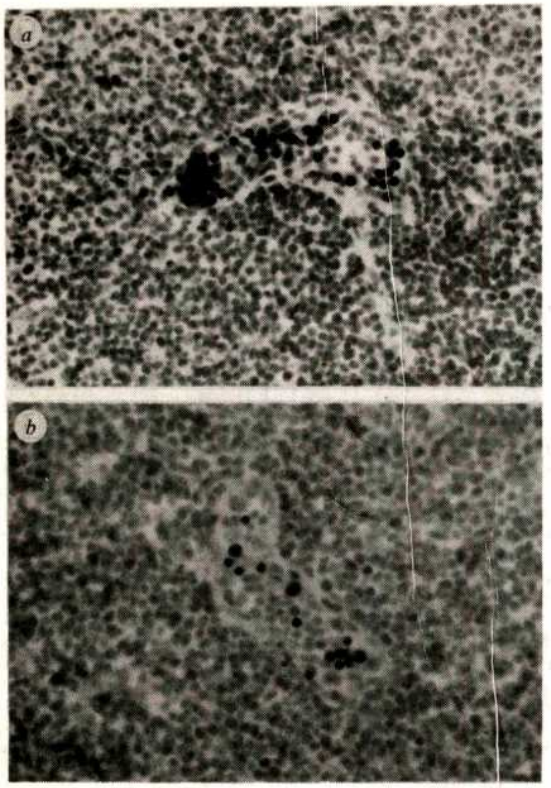

Fig. 2 Mouse (*a*) and chicken (*b*) lymphocytes (darker cells) adhering over HEV in frozen sections of mouse mesenteric lymph node (×200).

In addition to offering a plausible explanation for the observed relationship between SAI and evolutionary distance, this hypothetical model of steady evolutionary drift in interacting macromolecules predicts a similar exponential decline in interaction compatibility with increasing evolutionary separation in other systems. Examination of the ability of other simple, functionally conserved, cellular or molecular interactions to cross species barriers will test the general validity of this model. If verified, the model would imply that preservation of cellular and molecular interactions during evolution must be considered as a dynamic balance between mutation and selection, rather than static conservation.

Distribution of fibronectin in the ectoderm of gastrulating chick embryos

A GLYCOPROTEIN known as large external transformation-sensitive (LETS) protein, cell surface protein (CSP) or fibronectin[1–3] can be identified on the surface of various cell types[1]. This protein has a molecular weight of 210,000–250,000 and is closely related to the cold-insoluble globulin found in serum and to the factor needed for cell spreading *in vitro*[4,5]. In culture many cells secrete fibronectin into the growth medium and on to the substratum[6–8]; fibroblasts and other cells of mesodermal origin produce particularly large amounts. However, in the early mammalian embryo fibronectin is present in basement membranes before the mesoderm has formed, when the embryo consists only of ectoderm and endoderm[9]. Adult epithelia also produce fibronectin *in vitro*[10], and it forms a component of epithelial basement membranes *in vivo*[11–13]. We have applied an immunofluorescent technique to whole mounts of early chick embryos to examine the distribution and possible morphogenetic function of fibronectin. We discuss our results here, and suggest that fibronectin is involved in morphogenetic movement during early development.

Embryos between Hamburger and Hamilton stages 3 and 6 (ref. 14) were mounted as for New culture[15] and fixed in phosphate-buffered formol saline for at least 12 h. During fixation the endoderm was removed from the area pellucida and parts of the area opaca. In some cases portions of the developing mesoderm were also removed. The embryos were detached from the vitelline membrane and washed overnight with several changes of phosphate-buffered saline. Fibronectin was localised by indirect immunofluorescence[16,17] (Fig. 1).

Fibronectin was detected in association with all parts of the ectoderm and its distribution is shown in Fig. 1. A well defined fibrous meshwork was seen around the entire perimeter of the outer area opaca margins of the blastoderm (Fig. 2) as it expanded across the vitelline membrane. The vitelline membrane itself showed no specific fluorescence. The anterior half of the boundary between the area pellucida and area opaca

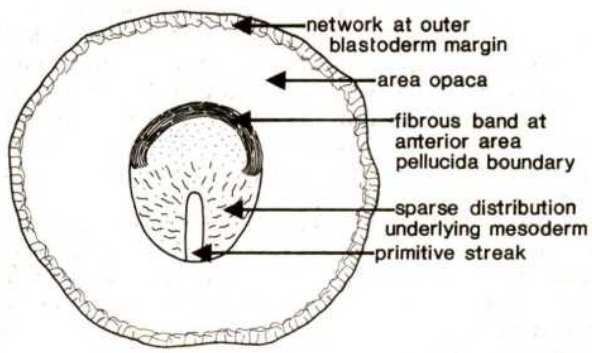

Fig. 1 Diagram to illustrate the overall distribution of fibronectin on the chick ectodermal basement membrane as detected by indirect immunofluorescence. The embryo is shown as if viewed from the ventral surface with the endoderm and mesoderm removed. Embryos were fixed in phosphate-buffered saline (PBS) containing 4% formaldehyde, and the endoderm and part of the mesoderm were removed by microdissection. They were then washed in PBS incubated at 37 °C for 30 min with rabbit anti-fibronectin antisera diluted 1:25 in PBS[16], and washed and incubated for a further 30 min with fluorescein isothiocyanate-labelled goat anti-rabbit (Miles) diluted 1:10. The embryos were washed with PBS, mounted ventral side uppermost on slides in 50% glycerol, and examined in a Zeiss photomicroscope. Phase contrast optics were used to identify particular areas of the embryos and epifluorescence UV illumination to visualise the fibronectin. Photographs were taken using Ilford HP5 film (400 ASA) and the sensitivity increased to 1,600 ASA by developing with Microphen (Ilford). Exposure time was 30–120 s. A total of 23 embryos were examined. Controls included substituting the rabbit anti-fibronectin antisera with pre-immune rabbit sera or using rabbit anti-fibronectin antisera which had been passed through a fibronectin–Sepharose affinity column[17]. In all cases the controls showed only a low background fluorescence.

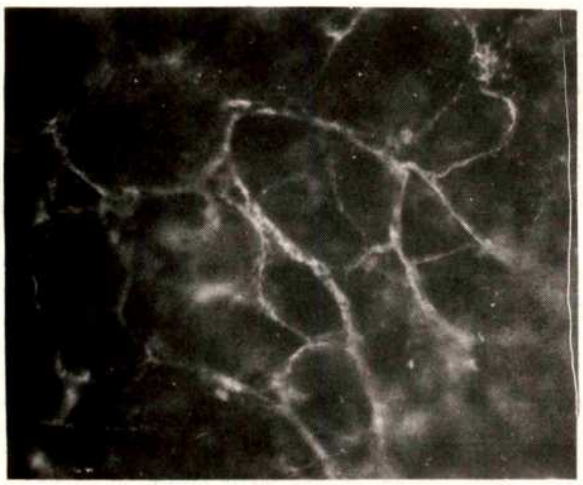

Fig. 2 Immunofluorescence demonstration of fibronectin at the outer margin of the chick blastoderm. Fluorescent fibres form a network (×990).

was outlined by an intensely fluorescent band of parallel fibres. This band was thickest in the midline anteriorly and gradually tapered as it extended posteriorly, terminating on a level with Hensen's node. Fluorescent granular deposits were present between the fibres (Fig. 3). The area pellucida on either side of the primitive streak is normally occupied by mesoderm, overlying the ectoderm. The mesoderm itself showed no specific fluorescence but if it was dissected away fibronectin could be detected on the underlying ectoderm. However, the fibronectin appeared poorly organised, the fluorescence being diffuse, with only occasional long thin fibres running mainly at right angles to the embryonic axis (Fig. 4). Between the mesoderm and the anterior boundary of the area pellucida is the proamnion, which is without mesoderm. Fluorescence there appeared as short thick disconnected rods. A very sparse and weakly fluorescent fibrous network of fibronectin was seen on the endoderm.

The fluorescence profile described above was not observed if rabbit anti-fibronectin was omitted during the staining procedure or if it was substituted with preimmune rabbit serum or rabbit antifibronectin antibodies which had previously been passed through a fibronectin–Sepharose column.

The distribution of fibronectin which we have observed in the early chick embryo can be linked to two known functions of the protein *in vitro*. First, its presence in cultures seems to facilitate cell movement[18], and second, it mediates the spreading of cells on substrates[19] and their attachment to collagen[20], although its function in the last respect may not be absolutely specific[21]. The situations in which we have observed accumulations of fibronectin in the embryo are those particularly associated with

Fig. 3 Immunofluorescence photograph of part of the fibrous band at the anterior area pellucida/area opaca boundary. The fibres are intensely fluorescent, run parallel to each other and are accompanied by particulate fluorescent material (arrows) (×900).

morphogenetic movement. All the outer margins of the blastoderm the area opaca ectoderm is active in locomotion. The outer margins of the blastoderm are responsible for the expansion of the blastoderm across the vitelline membrane so that ultimately the egg yolk is enclosed in the yolk sac[22]. This movement is associated with a high concentration of fibronectin around the marginal ectoderm cells.

The distribution pattern of fibronectin demonstrated by immunofluorescence also coincides closely with a distribution pattern of fibres seen on the ectodermal basement membrane in the area pellucida and area pellucida/area opaca boundary zone by scanning electron microscopy (SEM)[23,24] (Fig. 5). This pattern can be correlated with two separate morphogenetic movements, those of the mesoderm and of the primordial germ cells.

Immunofluorescence demonstrates fibronectin on the ectoderm surface underlying the mesoderm. Mesoderm cells reach their position between the ectoderm and endoderm by descending through the primitive streak and moving laterally out from the streak, across the area pellucida and eventually into the lateral and posterior area opaca, using the ectodermal basement membrane as a substrate[25–27]. Mesoderm cells reach the area opaca in front of the area pellucida by migrating around the anterior boundary between the area pellucida and area

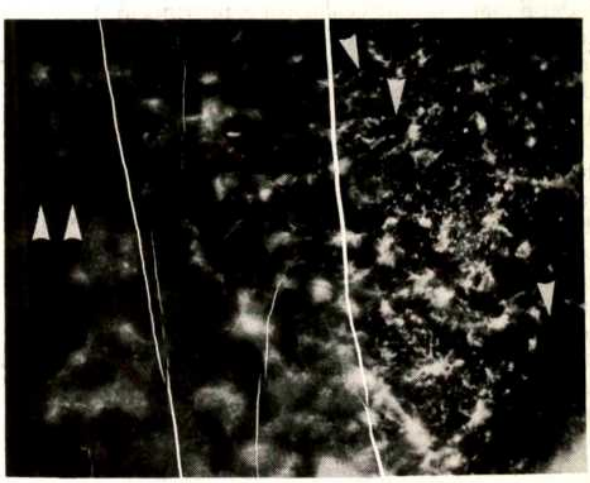

Fig. 4 An area from near the posterior end of the area pellucida. On the left side of the picture the mesoderm is only very faintly and diffusely stained. Removal of mesoderm as on the right reveals bright fluorescence, mainly finely dispersed but also as very thin fibres (arrows). The double arrow marks the embryonic axis (×340).

opaca. This boundary contains a particularly high concentration of fibronectin. The same boundary zone constitutes the germinal crescent. Primordial germ cells form there by detaching from the endoderm. The germ cells then move posteriorly around the germinal crescent to make contact with the developing vitelline vessels, reaching the gonads through the circulation[28,29]. They have therefore moved against the main direction of mesodermal migration around the anterior area pellucida boundary. A high concentration of fibronectin in the germinal crescent may assist the germ cells in this specific migration, and in fact, SEM reveals contacts between primordial germ cells and the fibrous band in the germinal crescent[23]. The developmental stage at which the fibronectin pattern is maximally defined is further evidence that its function is linked to morphogenetic movements. Mesoderm cells enter the anterior boundary zone between the area pellucida and area opaca after Hamburger and Hamilton stage 5 (refs 14, 30). Immediately before this stage the band as seen by immunofluorescence and SEM becomes most prominent[23], but after the entry of mesoderm into the boundary zone it becomes disorganised. Thus, the band has a transient existence coinciding closely with the time at which the anterior border of the area pellucida is a particularly active site of cell movement.

Fibronectin is present in the greatest quantity and in the most highly organised arrangement in the germinal crescent and

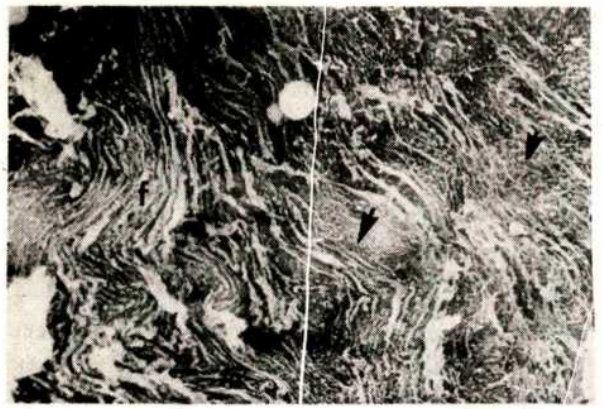

Fig. 5 Scanning electron micrograph of a portion of the fibrous band encircling the anterior boundary between area pellucida and area opaca in a stage 4 embryo. The band consists of rough-surfaced fibres in a parallel arrangement (f). They are accompanied by some loose granular material (arrows) (×1,275).

around the perimeter of the blastoderm. Both these sites are free of mesoderm cells at the time of our observations. At the blastoderm margins only ectoderm is present; in the germinal crescent the ectoderm is associated with endoderm.

We suggest that the fibronectin pattern is laid down by the ectoderm either alone or in association with endoderm and that its function is to facilitate certain morphogenetic movements in early development. First, it is involved in the overall expansion of the blastoderm across the vitelline membrane. Second, fibronectin contributes to a contact guidance system laid down by the ectoderm and utilised by primordial germ cells and mesoderm cells. The cells would tend to move along pathways of fibronectin because of the effects of the protein in favouring cell spreading and locomotion. Further work is in progress to observe these movements directly in living embryos.

Insulin-receptor antibodies mimic a late insulin effect

AUTOANTIBODIES against the insulin receptor are found in patients with a rare form of extreme insulin resistance associated with acanthosis nigricans[1]. These antibodies are primarily polyclonal IgGs, compete with insulin for binding to its receptor[2,3], immunoprecipitate solubilised insulin receptors[4], and have been used as probes of insulin action. The acute action of the antibodies is to mimic many of insulin's biological effects, particularly those which occur rapidly after hormone binding to its cell-surface receptors[5–9]. In addition, insulin exerts biological effects which appear more slowly. For example, insulin treatment of 3T3-L1 fatty fibroblasts increases the activity of lipoprotein lipase maximally after 2–4 d but is without effect during the first 4 h (refs 10, 11). Some investigators have suggested that these slower effects may be mediated by different mechanisms from those involved in the production of the acute effects[12,13]. We now report that autoantibodies against the insulin receptor mimic this long-term insulin effect on lipoprotein lipase.

3T3-L1 fatty fibroblasts exposed for 24 h to increasing concentrations of partially purified anti-receptor antibodies showed a dose-dependent increase in the activity of lipoprotein lipase (Fig. 1*a*). Significant stimulation of enzyme activity was observed with as little as 3.5 $\mu g\ ml^{-1}$ anti-receptor antibodies and the effect was maximal with 35 $\mu g\ ml^{-1}$ IgG, reaching 65% of the response induced by a maximal stimulatory insulin concentration (1 $\mu g\ ml^{-1}$). In contrast, normal IgG had no stimulatory effect on the activity of the enzyme. However, with very high concentrations of anti-receptor antibodies (350 $\mu g\ ml^{-1}$) the stimulatory activity decreased. This seems to be due to a nonspecific effect of these preparations on the cells or enzyme system, as the same high concentration of normal IgG produced a similar decrease in basal enzyme acitivity (Fig. 1*a*) and diminished the stimulatory effect of high insulin concentrations (data not shown).

As previously demonstrated, the effect of insulin on lipoprotein lipase activity in 3T3-L1 fatty fibroblasts is a slow phenomenon, requiring 12 h for half-maximal insulin stimulation[10,11]. Similarly, the stimulatory effect of the anti-receptor antibodies is characterised by a slow time course of induction (Fig. 1*b*). After 12 h a maximally effective concentration of anti-receptor antibodies (35 $\mu g\ ml^{-1}$) was about equipotent to a maximally effective insulin concentration (1 $\mu g\ ml^{-1}$) in stimulating the lipoprotein lipase activity. The maximal increase in the enzyme activity in the presence of this most potent antibody concentration was observed after 24 h of exposure, and in contrast to the effect of insulin, stimulation by the antibodies then tended to decline. This is probably due to a desensitisation of the biological response at post-receptor sites observed with chronic antibody exposure, but not with insulin. We observed a similar phenomenon when studying the effect of the same antibody preparations on glucose transport and oxidation in 3T3-L1 fatty fibroblasts[7]. Thus, acute exposure of these cells to anti-receptor antibodies resulted in a stimulation of 2-deoxyglucose transport and glucose oxidation, whereas after prolonged exposure basal glucose metabolism returned to control levels. This occurred without change in the ability of the antibodies to inhibit insulin binding. Our interpretation of these data is that despite persistent occupancy of the insulin receptor the anti-receptor antibodies are unable to produce a continuing signal for generation of the biological effects.

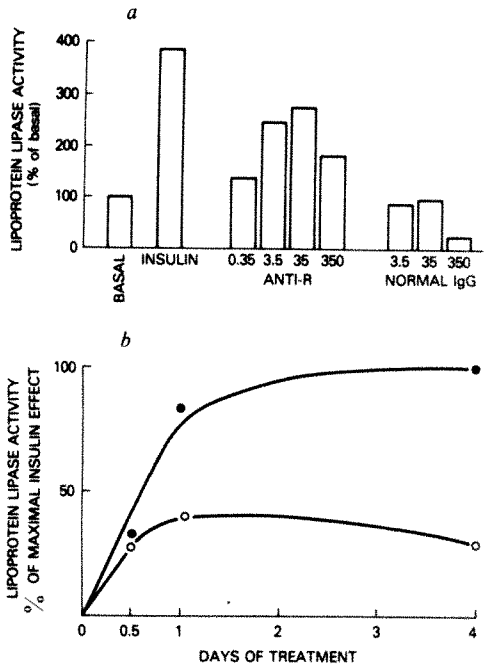

Fig. 1 *a*, Stimulation of lipoprotein lipase in 3T3-L1 fatty fibroblasts by increasing concentrations of antibodies against the receptor for insulin 3T3-L1 cells were isolated by Dr Howard Green and provided by him and Dr Ora M. Rosen[14–16]. Fibroblasts were grown to confluence in Petri dishes with Dulbecco–Vogt's minimal essential medium containing 10% fetal calf serum. After confluence they were treated with media supplemented with 1-methyl-3-isobutylxanthine (0.5 mM) and insulin (1 μg ml^{-1}) for 2 d followed by insulin alone for 4 d to enhance conversion to fatty fibroblasts. Thereafter, cells were cultured for 4 d in Dulbecco–Vogt's minimal essential medium containing 5% fetal calf serum. The fatty fibroblasts were then exposed to insulin (1 μg ml^{-1}), partially purified antibodies against the receptor for insulin, or normal IgG. After 24 h the activity of the enzyme lipoprotein lipase was measured in the cells as described by Spooner *et al.*[17]. One unit of lipoprotein lipase is defined as the amount of enzyme that releases 1 μM of ^{3}H-oleic acid per min at 37 °C from a serum-activated emulsion of ^{3}H-trioleoylglycerol and L-α-phosphatidylcholine. The partially purified antibodies against the receptor for insulin were prepared as follows. Plasma from a patient (patient B-2) with insulin resistance of the type B syndrome[1], containing a high titre of antibodies against the receptor for insulin (1:2,000), was treated with 33% ammonium sulphate. The precipitate was dissolved in and dialysed against 0.05 M sodium phosphate buffer, *p*H 7.4, containing 0.15 M NaCl, to a protein concentration of 10 mg ml^{-1} (based on absorbancy measurements assuming $A^{1\%}_{280\,cm} = 12$). This preparation is referred to as anti-R. The preparation referred to as normal IgG was obtained from plasma from a normal person using the same procedure. Results in this and all subsequent figures represent means of duplicate activity measurements each on three to six individual plates of cells. The data are expressed as per cent of basal lipoprotein lipase activity which was 0.27 ± 0.05 U per mg cell DNA (mean ± s.e.m.; $n = 4$). Lipoprotein lipase activity in the presence of insulin, 1.03 ± 0.06 U per mg DNA ($n = 4$), was statistically different from the basal activity at the $P < 0.001$ level using Student's *t*-test. Activity in the presence of 3.5 and 35 μg ml^{-1} anti-R was 0.69 ± 0.08 ($n = 4$) and 0.77 ± 0.07 U per mg DNA ($n = 4$) respectively; both values are statistically different from basal activity ($P < 0.01$). Activity in the presence of 350 μg ml^{-1} anti-R, 0.49 ± 0.05 ($n = 4$), was marginally significant ($0.05 < P < 0.10$). *b*, Time course of insulin (●) and anti-R (○) induced stimulation of lipoprotein lipase activity in 3T3-L1 fatty fibroblasts. 3T3-L1 fatty fibroblasts were exposed for 0.5, 1 and 4 d to either insulin (1 μg ml^{-1}) or antibodies against the receptor for insulin (35 μg ml^{-1}). At the end of treatment, activity of lipoprotein lipase in cells was measured and expressed as per cent of the maximal insulin stimulation above basal activity. Basal lipoprotein lipase activity was 0.33 ± 0.02 U per mg DNA ($n = 3$). The activity in cells treated with insulin and anti-R was, respectively, 0.65 ± 0.05 ($n = 3$) and 0.59 ± 0.04 U per mg DNA ($n = 3$) after 0.5 d of treatment; 1.16 ± 0.08 ($n = 3$) and 0.72 ± 0.03 U per mg DNA ($n = 3$) after 1 d; 1.33 ± 0.17 ($n = 3$) and 0.60 ± 0.02 U per mg DNA ($n = 3$) after 4 d. Stimulation of lipoprotein lipase activity by insulin and anti-R was statistically significant at all time points ($P < 0.01$).

To determine whether stimulation of lipoprotein lipase by anti-receptor antibody was mediated by mechanisms similar to those involved in the action of insulin, 3T3-L1 fatty fibroblasts were pretreated for 60 min at 37 °C with anti-receptor antibodies and then exposed to increasing concentrations of insulin for 24 h at 37 °C (Fig. 2). As shown above, anti-receptor antibody alone produced a 60% increase in the activity of the enzyme. Addition of insulin at concentrations up to 10^{-6} M produced minimal further effects on the antibody-treated cells. This blockade of the insulin effect suggests that both insulin and the anti-receptor antibody use the same pathway for the production of this biological response. The small increment in the activity of the enzyme observed after the addition of high insulin concentrations is probably due to the fact that in this experiment a low antibody concentration was used, which inhibited insulin binding by only 70%.

Additional evidence that this chronic effect of anti-receptor antibodies is similar to that of insulin was obtained in studies with cycloheximide (Fig. 3). Cycloheximide, in experimental conditions in which protein synthesis was reduced by 90%, inhibited the insulin-induced increase in lipoprotein lipase activity. Similarly, the stimulatory activity of the anti-receptor antibodies on lipoprotein lipase was abolished by cycloheximide. Thus, in addition to their short-term insulin-like effects, the anti-receptor antibodies can mimic a long-term insulin effect.

The present observations have important implications for the mechanism of insulin action. Current studies have suggested two possible pathways to explain the long-term effects of insulin. First, as we have previously suggested[9,24], all the information required for the generation of the biological effects of insulin could be present in the receptor molecule itself. In this case, both insulin and the antibodies against the insulin receptor would generate an activated receptor which would then mediate insulin's effect either directly or by generation of the same second messenger as that for insulin. Alternatively, after binding to the cell-surface receptors, insulin and the anti-receptor antibodies are endocytosed and subsequently the ligands or their degradation product(s) bind to intracellular insulin receptors, which elicit the late insulin effect. The recent observation that insulin and/or the insulin–receptor complex enter target cells[18,19] and the demonstration of specific binding sites for insulin on intracellular organelles[20–23] have been taken as evidence that this last pathway may be more important.

The present results and the above-mentioned data suggest that the second hypothesis is rather unlikely. Indeed, indirect studies have indicated that the antibodies against the insulin receptor bind very poorly to intracellular receptors[25]. Furthermore, it seems very unlikely that two totally different polypeptides, insulin and anti-receptor antibodies, would generate an identical or similar degradation product, which would

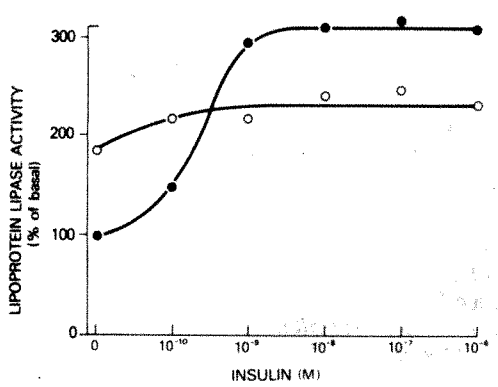

Fig. 2 Effect of antibodies against the receptor for insulin on the insulin-induced stimulation of lipoprotein lipase activity. 3T3-L1 fatty fibroblasts were pretreated for 1 h with either normal IgG (1.75 μg ml^{-1}) or anti-R (1.75 μg ml^{-1}). Increasing concentrations of insulin (0–10^{-6} M) were then added and the incubation continued for a further 24 h. Lipoprotein lipase activity was determined and expressed as per cent of basal. Basal lipase activity was 0.52 ± 0.13 U per mg DNA ($n = 6$). Activities in the presence of 10^{-6} M insulin alone and anti-R alone were 1.61 ± 0.10 ($n = 4$) and 0.95 ± 0.04 U per mg DNA ($n = 6$), respectively. Both values are statistically different from that of basal activity ($P < 0.001$). Lipoprotein lipase activity in cells exposed to anti-R and then 10^{-6} M insulin (1.21 ± 0.07 U per mg DNA, $n = 4$) (○) was statistically different from the activity in cells treated with 10^{-6} M insulin alone ($P < 0.05$) (●).

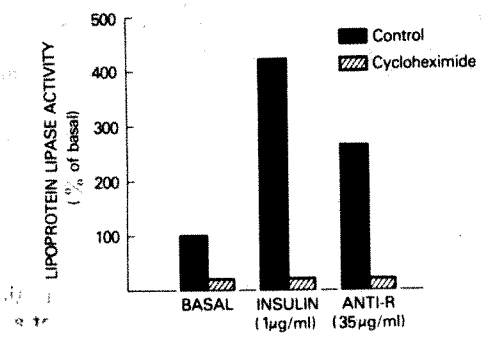

Fig. 3 Effect of cycloheximide on the lipoprotein lipase response to insulin and to antibodies against the receptor for insulin. 3T3-L1 fatty fibroblasts were incubated in basal growth medium with or without insulin (1 $\mu g\ ml^{-1}$) or anti-receptor antibodies (35 $\mu g\ ml^{-1}$) in the absence (control) or presence of cycloheximide (4×10^{-7} M) for 24 h. The data are expressed as per cent of the basal activity observed in control cells. Basal lipoprotein lipase activity in control cells was 0.47 ± 0.05 U per mg DNA ($n = 3$). Activity in the presence of insulin and anti-R was 1.99 ± 0.12 ($n = 3$) and 1.26 ± 0.07 U per mg DNA ($n = 3$), respectively. Both values are significantly different from that of basal activity ($P < 0.001$). In the presence of cycloheximide, lipase activity in insulin and anti-R treated cells was significantly reduced to 0.08 ± 0.01 and 0.09 ± 0.01 U per mg DNA, respectively ($P < 0.001$, $n = 3$).

produce late insulin effects by binding to intracellular insulin receptors. Therefore, our present data favour the idea that both insulin and the anti-receptor antibody generate the same second messenger(s) or alternatively, that they both lead to the endocytosis of the insulin receptor, and the receptor itself contains all the necessary information for the generation of the late effects of the hormone.

Finally, it should be noted that we have dealt here only with acute and chronic 'metabolic' responses to insulin. Insulin, and several other insulin-like peptides, also produce long-term 'growth' responses, such as stimulation of thymidine incorporation into DNA. Whether these effects of insulin are mediated by a different mechanism or even the interaction of insulin with a different membrane receptor, remains to be determined.

β-Adrenoreceptors determine affinity but not intrinsic activity of adenylate cyclase stimulants

SIGNIFICANT progress has recently been made toward defining and understanding the molecular basis of hormone sensitivity in the β-adrenoreceptor-adenylate cyclase system. Through the use of biochemical[1,2] and genetic[3,4] techniques it has become apparent that this system is comprised of at least three separate components: the β-adrenoreceptor, which is responsible for the binding of β-adrenergic agents; the catalytic unit of the enzyme adenylate cyclase, responsible for the conversion of ATP to cyclic AMP; and a nucleotide regulatory component or components which seems to possess a GTPase activity[5] and to be required for coupling of the β-adrenoreceptor to the adenylate cyclase enzyme[6]. As has been demonstrated by Orly and Schramm[7] and confirmed by Schwarzmeier and Gilman[8] in cell fusion experiments, these components interact to produce the hormone-responsive adenylate cyclase system and this interaction occurs even when the separate functions are donated by heterologous cell types. Frog and turkey erythrocytes each possess a catecholamine-responsive adenylate cyclase. Although similar in some respects these two well-studied systems differ markedly with respect to their drug affinities and intrinsic activities. Intrinsic activity is defined as the maximal ability of a drug to stimulate a biological or biochemical response. To elucidate the role of the β-adrenoreceptor in the expression of these properties, we report here the use of cell fusion techniques to construct a hybrid which possesses the β-adrenoreceptor of the turkey erythrocyte and the adenylate cyclase of the frog erythrocyte. The characteristics of this hybrid indicate that although the receptor determines relative drug affinities (for example, β_1 compared with β_2 subtypes of receptor), it is a component distal to the receptor which determines relative drug intrinsic activities.

Hybrid cells were constructed by fusing frog erythrocytes, the β-adrenoreceptor of which had been inactivated with dicyclohexyl carbodiimide, with turkey erythrocytes, the adenylate cyclase of which had been inactivated by treatment with *N*-ethyl maleimide (Fig. 1 legend). Under the conditions used to inactivate the β-adenoreceptor of the frog erythrocyte the ability of catecholamines to stimulate adenylate cyclase is totally abolished, whereas only 25–30% of basal, fluoride-, and Gpp(NH)p-stimulated adenylate cyclase activity is lost. The fact that the adenylate cyclase in these treated cells remains responsive to Gpp(NH)p indicates the functional presence of the nucleotide regulatory component as well as the catalytic unit of adenylate cyclase.

In the turkey erythrocyte treatment with *N*-ethyl maleimide results in >99% inactivation of control adenylate cyclase activity. However, when assayed for catecholamine-stimulated GTPase activity according to the method of Cassel and

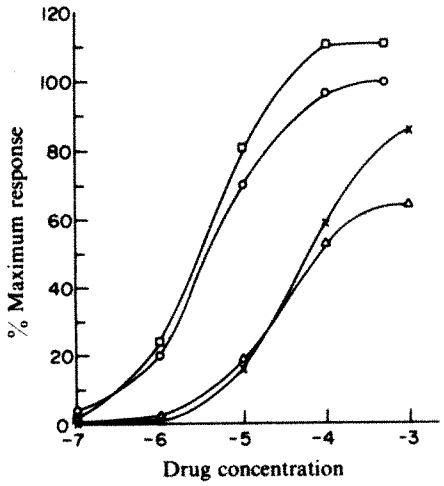

Fig. 1 Dose–response curves of agonists for stimulation of adenylate cyclase in hybrid cell membranes. □, Hydroxybenzylisoproterenol; ○, isoproterenol; ×, adrenaline; △, noradrenaline. The β-adrenoreceptor of the frog erythrocyte was inactivated by treatment of whole cells with 50 M dicyclohexyl carbodiimide (DCCD) for 30 min at 30 °C as described previously[9]. The adenylate cyclase of the turkey erythrocyte was inactivated by treatment of the whole cells with 5 mM *N*-ethyl maleimide (NEM) for 30 min at 0 °C, followed by three washes with buffered saline. Sendai virus was grown according to Watkins[10]. For cell fusion 1×10^9 NEM-treated turkey cells and 2×10^8 DCCD-treated frog cells were mixed in 10 ml buffer containing 135 mM KCl, 5 mM NaCl, 0.8 mM $MgCl_2$, 2 mM $MnCl_2$ and 20 mM Tris-HCl at *p*H 7.4. Approximately 5–10,000 haemagglutinating units of inactivated Sendai virus was added to the cell suspension which was incubated on ice for 10 min and then transferred to a 37 °C water bath for 30–60 min. Normally after microscopical examination of an aliquot of these cells, 50–75% of the nuclei were in polykargons with greater than 95% of the giant cells containing at least one nucleus (determined by relative nucleus size) of each cell type. Membranes were prepared using a freeze-thaw lysis technique[11] and adenylate cyclase activity was assayed as described previously[12,13] with the exception that the final assay mixture contained 0.3 mM ATP and 0.1 mM GTP. For each fusion experiment a 'mixed control' was run in which the appropriate number of DCCD-treated frog and NEM-treated turkey cells were mixed, incubated in fusion buffer without virus, and assayed for adenylate cyclase activity. In no case was isoproterenol-stimulated enzyme activity observed in this preparation. In addition, homologous control fusions of DCCD-treated frog cells and NEM-treated turkey cells did not result in the appearance of hormone-sensitive adenylate cyclase, nor did fusion of wild type frog erythrocytes or wild type turkey erythrocytes with themselves alter the patterns of agonist affinities or intrinsic activities. Maximum response refers to adenylate cyclase activity in the presence of 10^{-4}M isoproterenol and represents an average of 118.3 pmol cyclicAMP per mg protein per 10 min over a basal activity of 45.1 pmol per mg protein per 10 min. The EC_{50} values for the agonists for the activation of adenylate cyclase are: hydroxybenzylisoproterenol 4×10^{-6}M; isoproterenol 4×10^{-6}M; adrenaline 4×10^{-5}M; noradrenaline 3×10^{-5}M. EC_{50} is defined as the concentration of agonist required to elicit 50% of the maximal stimulation of adenylate cyclase produced by that particular drug. The curves shown are the average of four separate experiments.

Sellinger[14], membranes derived from these treated cells exhibited only a 15–20% loss of catecholamine-stimulated GTPase activity. Thus, these cells seem to possess both the β-adrenoreceptor and the nucleotide regulatory protein.

In the turkey erythrocyte catecholamine agonists demonstrate a β_1 order of potency (isoproterenol > noradrenaline ≈ adrenaline) for the activation of adenylate cyclase[15]. In the frog erythrocyte, however, a β_2 pattern (isoproterenol > adrenaline > noradrenaline) of catecholamine agonist potencies is observed[16]. This definition of β-adrenoreceptor subtypes has been set forth by Lands[17]. Shown in Fig. 1 are the dose–response curves of four β-adrenoreceptor agonists for stimulating adenylate cyclase activity in membranes derived from hybrid cells. The preparation demonstrates a typical β_1 adrenoreceptor specificity for these agonists. Isoproterenol is more potent than noradrenaline and adrenaline which are approximately equipotent. In addition, hydroxybenzylisoproterenol, a β_2-specific agonist, which is tenfold more potent than isoproterenol in the frog β_2 system[18] exhibits the β_1 characteristic of equipotency with isoproterenol in the hybrid cells (L. J. Pike and R. J. Lefkowitz, unpublished results).

As the parental turkey erythrocyte adenylate cyclase and the frog erythrocyte β-adrenoreceptor have been completely inactivated, the observation that β- agonists can stimulate adenylate cyclase activity in this system suggests that a hybrid receptor–adenylate cyclase has been constructed. The β_1 specificity of the agonist response indicates that the relative affinities of β-adrenergic agents are determined by the receptor protein itself.

To determine whether the receptor was also responsible for determining the intrinsic activities exhibited by agonist drugs, the maximal ability of a series of adrenergic drugs to stimulate the adenylate cyclase in hybrid membrane preparations was examined. The results of these studies are shown in Table 1.

It can be observed that in all cases the intrinsic activities in the hybrid closely resemble those of the frog system. Particularly striking differences between agonist intrinsic activities in the turkey and frog erythrocyte are seen for noradrenaline, cobefrin and isoetharine. In each of these instances the hybrid system's response is similar to that of the frog. For all the drugs tested, the hybrid intrinsic activities are not significantly different from the frog erythrocyte intrinsic activities (on the basis of Student's *t* tests), whereas the hybrid intrinsic activities are significantly different ($P < 0.01$) from those of the turkey erythrocyte. As the intrinsic activities parallel those of the adenylate cyclase donor rather than the receptor donor, it seems that some component distal to the receptor is responsible for determining intrinsic activity.

In our current conceptualisation of the system this distal component might be either the nucleotide regulatory component, catalytic unit of adenylate cyclase, or both. It is evident that only the frog erythrocyte catalytic adenylate cyclase unit is active in the hybrids. However, the hybrids seem to contain both turkey and frog nucleotide components. Thus, it is unclear what role the nucleotide regulatory component(s) might play in the determination of intrinsic activity, as one or both might be functioning in the hybrid.

Table 1 Intrinsic activities of β-adrenergic agents in membrane preparations of frog, turkey and hybrid erythrocytes

Agonist	Intrinsic activity		
	Hybrid	Frog	Turkey
(−)Isoproterenol	1.00 (9)	1.00 (4)	1.00 (4)
(−)Adrenaline	0.87 ± 0.03 (9)	0.95 ± 0.02 (3)	1.00 ± 0.01 (3)
(−)Noradrenaline	0.62 ± 0.03 (9)	0.54 ± 0.02 (4)	1.00 ± 0.02 (4)
(±)Cobefrin	0.50 ± 0.01 (4)	0.47 ± 0.03 (4)	0.92 ± 0.03 (4)
(±)Isoetharine	0.35 ± 0.04 (5)	0.42 ± 0.01 (3)	0.71 ± 0.02 (3)
(−)Soterenol	0.13 ± 0.02 (5)	0.11 ± 0.01 (3)	0.44 ± 0.04 (3)
Dobutamine	0.07 ± 0.01 (5)	0.07 ± 0.01 (3)	0.19 ± 0.01 (3)

Control frog and turkey intrinsic activities were assessed using fused frog and fused turkey erythrocytes prepared in the same manner as the hybrid erythrocytes. To determine intrinsic activities several concentrations of each drug over a 20-fold range bracketing the saturation point were assayed for stimulation of adenylate cyclase activity. The highest activity observed (minus basal) for each was divided by the maximal activity (minus basal) observed in the presence of saturating concentrations of isoproterenol and the values are reported as this fraction. Activities were (pmol cyclicAMP per mg protein per 10 min): basal 183; isoproterenol 3108 in the frog; basal 7.6; isoproterenol 99.1 in the turkey; and basal 45.1; isoproterenol 118.3 in the hybrids. The values given are the mean ± g.e.m. of the number of experiments shown in parentheses.

The construction of a hormone-sensitive adenylate cyclase system containing components from the frog and turkey erythrocyte systems has allowed us to assess the possible role of the β-adrenoreceptor in the determination of the affinities and intrinsic activities of drugs. As has been previously observed by others[7,8,19] we find that the receptor molecule seems to confer β-adrenoreceptor specificity to an adenylate cyclase system. In addition, however, the receptor also determines the relative affinities of β-adrenergic agents. Thus, the specificity observed in the β_1/β_2 subtypes most likely arises from slight differences in receptor protein structure. Interestingly, however, these data indicate that it is not the receptor but rather some component(s) distal to it that is responsible for the determination of intrinsic activity. Characterisation of the reciprocal hybrid (*N*-ethyl maleimide frog cell crossed with dicyclohexyl carbodiimide treated turkey cell) would further elucidate this point. However, to date all attempts to construct a functional hybrid of this composition have been unsuccessful.

The reconstitution of a catecholamine-stimulated adenylate cyclase system using cell fusion of these two different but complementary cell types is a potentially powerful tool that will be useful in defining the molecular components responsible for a variety of system characteristics such as desensitisation and the differing patterns of nucleotide regulation of adenylate cyclase activation.

Acetylcholinesterase like that of skeletal muscle in smooth muscle reinnervated by a motor nerve

SKELETAL muscles contain several molecular forms of acetylcholinesterase (AChE) characterised by different sedimentation coefficients[1–4]. In rat muscle[1,2] (but not human[3] and chicken[5] muscle) the heavy form of AChE is exclusively present at the motor endplate regions. In contrast, the heavy form of AChE has not been detected in cat[6] or rat[2] smooth muscles. The endplate AChE of rat skeletal muscle is selectively detached by treatment with collagenase[1,7], an enzyme which has been shown specifically to digest the collagen-like tail of the heavy form of AChE from several sources[8,9]. The presence of endplate AChE is neurally regulated[10], and there is evidence that this effect is partially mediated by muscle activity[11] and by a trophic factor conveyed by axoplasmic transport[12,13]. Previous results from our laboratory have shown that reinnervation of the cat nictitating membrane smooth muscle by a motor nerve results in an increase of AChE activity[14]. We report here that collagenase treatment detaches active AChE from cat smooth muscle reinnervated by a cholinergic motor nerve, and that a new AChE form with a high sedimentation coefficient is induced in these muscles. Our results suggest that the presence of the motor nerve determines, in reinnervated smooth muscle, the appearance of an AChE similar to that found in skeletal muscle.

The superior cervical sympathetic ganglion was removed from adult cats, the hypoglossal nerve was sectioned and the central stump sutured to the postganglionic fibres of the superior cervical ganglion. Details of the experimental procedure are given elsewhere[14]. Seven months post-operation, both the hypoglossal and the preganglionic nerves were stimulated to confirm that smooth muscles had been reinnervated exclusively by the hypoglossal. In all cases, the nictitating membrane and the pupil responded only to hypoglossal stimulation. The inferior smooth muscles of both nictitating membranes were then removed for AChE assay[15]. In one series, control and reinnervated muscles were incubated *in vitro* at 37 °C in a medium[16] containing 0.2 mg ml^{-1} collagenase (preparation type III, 400 U mg^{-1}, Sigma). We used the collagenase digestion technique which is known to detach selectively AChE from the motor endplates, leaving the non-endplate AChE intact[7]. In another series of experiments, homogenates of reinnervated and normal smooth muscle were sedimented in a linear (5–20%) sucrose gradient following the method of Martin and Ames[17]. Sucrose solutions (Schwarz–Mann, special enzyme grade) containing NaCl-Triton X-100 were used[1]. The specific activity of AChE in control muscles was 0.57 nmol ^{3}H-acetate formed per min per mg protein, while in reinnervated muscles it increased to 1.23. Smooth muscles reinnervated for a longer period (10 months) showed a higher AChE level, reaching a specific activity of up to 3.1 (ref. 18).

Reinnervated smooth muscles incubated with collagenase released an amount of AChE proportional to the time of incubation whereas control muscles showed no solubilised AChE activity (Fig. 1). It is known that collagenase disrupts the muscle fibre basement membrane[19,20], and releases motor endplate AChE which is partly localised within the basal lamina at the neuromuscular junction[21]. The enzymatic detachment of active AChE from reinnervated smooth muscle suggests that this new enzyme form is probably anchored to a basal lamina-like material—as has been proposed for AChE forms which present sensitivity to collagenase[8]—and would correspond to a high sedimentation coefficient form, similar to the AChE form specific for rat motor endplate[1]. The AChE release experiments, however, do not yield definite structural information since commercial collagenases are contaminated with several proteases[22]. The molecular forms of AChE present in reinnervated smooth muscle were therefore identified by velocity sedimentation analysis. Figure 2 shows that a new heavy form of AChE appears in smooth muscle reinnervated by a cholinergic motor nerve. This heavy form of AChE which probably corresponds to the asymmetric form A_{12} of Bon *et al.*[8], accounts for 9% of the total activity and represents ~25% of the total AChE increase in reinnervated muscles. As the heavy form of AChE is not present in normal smooth muscle[6], it is likely that the species detached by collagenase corresponds to this high sedimentation coefficient form[23]. The present results show that a motor nerve can induce in smooth muscle a form of AChE similar to that found in skeletal muscle. As innervation by a cholinergic motor nerve is a common factor for reinnervated smooth muscle and skeletal muscle, our results suggest that the motor nerve is able to regulate AChE in any musculature it innervates.

Several different mechanisms could be involved in neural AChE regulation: (1) muscle activity; (2) acetylcholine itself; (3)

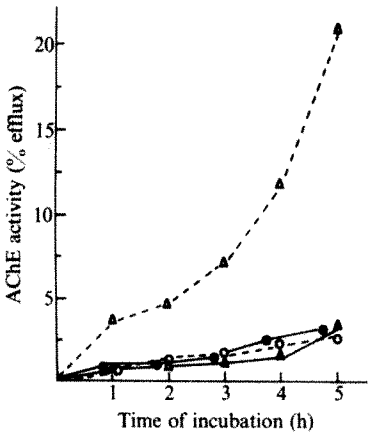

Fig. 1 Release of AChE from inferior smooth muscles of the nictitating membrane as a function of time of incubation. Experimental conditions: normal smooth muscle of the nictitating membrane with collagenase (○) and without collagenase (●), reinnervated smooth muscle of the nictitating membrane with collagenase (△) and without collagenase (▲). Smooth muscle samples (15–20 mg) were incubated at 37 °C in 300 μl of a medium containing 138 mM NaCl, 4 mM KCl, 1 mM $MgSO_4$, 50 mM sodium phosphate (*p*H 7.5), 0.1 mg ml^{-1} chloramphenicol, and 0 or 5 μM BW 284C51 dibromide. Collagenase (0.2 mg ml^{-1}) was added to the incubation medium of some of the muscle samples. At various times, duplicate aliquots of 10 μl incubation medium were removed for AChE assay[15]. Subsequently, the muscle samples were homogenised 1/15 (w/v) in ice-cold buffer *p*H 7.3 (1 M NaCl, 0 1% Triton X-100, 0.05 M Tris-HCl, 0.2 mM EDTA) to determine AChE activity. Untreated muscle samples were also homogenised and assayed for AChE. The absolute amount of AChE in incubated samples is not the same for the different experimental situations studied, therefore to evaluate comparatively the AChE release in each case[16] the initial amount of enzyme present in the samples must be taken into account. % AChE efflux:

$$\frac{(\text{AChE medium} \times 100\%)}{(\text{AChE medium} + \text{AChE in homogenate})}$$

release of AChE from the nerve terminal; and (4) neurotrophic control. These four mechanisms are discussed below:

(1) Muscle activity has been shown to play a role in modulating AChE in chick muscle culture[24], and stimulation of muscular activity can induce AChE spots in rat muscle[11]. The 16S AChE form reappears at the original endplates in denervated muscles, after reinnervation at a different site[25]. A possible explanation for this is that muscle activity stimulates synthesis or stabilisation of 16S AChE at sites on the muscle previously determined by nerve contact[25,26]. Lømo and Slater[11] suggest that muscle activity might turn on synthesis of junctional AChE in addition to turning off synthesis of extrajunctional acetylcholine receptors in rat skeletal muscle. We know that reinnervation of the nictitating membrane smooth muscle by a motor cholinergic nerve determines both a decrease in the hypersensitivity to acetylcholine[27], and the induction of a heavy form of AChE; hence, the effect suggested for muscle activity in skeletal muscle[11] might also apply in smooth muscle reinnervated by a motor nerve. Recently, however, it has been shown that, in the rat, the endplate 16S AChE form is influenced by the length of the nerve stump[28]. As muscles become inactive at the time of nerve section[29] regardless of the nerve stump length, it follows that the endplate 16S AChE form also depends on an activity-independent mechanism[28].

(2) Acetylcholine *per se* does not seem to be an important factor in AChE regulation: during reinnervation of skeletal muscle with preganglionic parasympathetic cholinergic fibres, AChE decreased and almost disappeared when reinnervation was completed, despite normal acetylcholine release[30].

(3) Release of neural AChE has been demonstrated in rat phrenic nerve–hemidiaphragm[31]. Although the motor nerve contains a heavy form of AChE[32,33], only the 10S form of AChE has been shown to be released from nerve terminals. Evidence that a heavy form of AChE is conveyed by axonal flow was obtained by studying the accumulation of material at the proximal stump of a damaged nerve[32], so it is possible that the heavy form of AChE is produced locally either in Schwann or other extra-axonal cells, at the site of the injured stump. In this context, it has been recently demonstrated that glial cell acid phosphatase is transported to damaged axons[34]. In any case, as the axonal flow is an important mediator in the neurotrophic regulation of junctional AChE[12], the motor nerve innervating the smooth muscle of the nictitating membrane could provide a source for the heavy form of AChE.

(4) AChE trophic substances[35,36] are conveyed by axoplasmic transport[12,13] and in motor nerves a trophic factor has been detected which is capable of maintaining the level of AChE in cultures of aneural embryonic muscle or denervated adult chicken muscle[36]. Moreover, a trophic factor, other than AChE, isolated from rat phrenic nerve and transported by axonal flow, has been shown to maintain the levels of endplate AChE in rat diaphragm tissue culture[13]. This finding strongly suggests that a substance different from AChE, conveyed by axonal flow to the nerve terminal, would be a major factor in the neurotrophic regulation of endplate AChE. The effect we observed in reinnervated smooth muscle may be partly mediated by a similar factor. Thus motor nerves regulate AchE, but parasympathetic

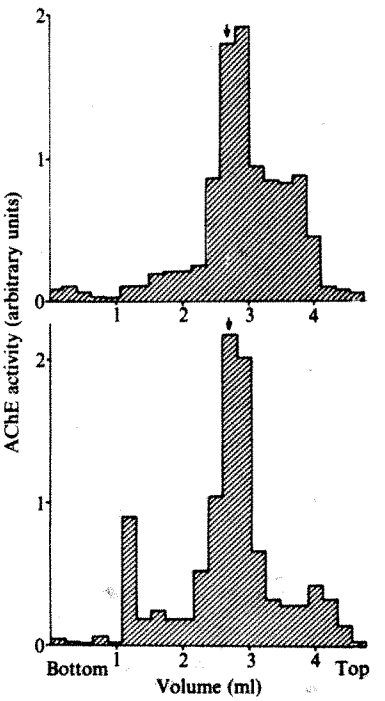

Fig. 2 Velocity sedimentation of smooth muscle extracts in a sucrose gradient. AChE activity profile of: *a*, control smooth muscle; *b*, reinnervated smooth muscle. Smooth muscles (~10 mg) were homogenised in ice-cold NaCl–Triton buffer, *p*H 7.3 (1M NaCl, 0.5% Triton X-100, 0.05M Tris-HCl, 0.2 mM EDTA). After various times of enzyme extraction, samples of 0.2 ml (2.4 mg protein) were layered on linear (5–20%) sucrose gradients, in the presence of the same buffer as for homogenisation and subjected to velocity sedimentation. Ultracentrifugation was performed in a Beckman L5-65 ultracentrifuge, with a SW 65 rotor at 39,000 r.p.m. for 12 h at 20 °C. A volume of 0.05 ml of each fraction was assayed for AChE activity. Activity was measured by a radiochemical procedure in which release of ^{3}H-acetate from ^{3}H-ACh iodide (NEN, 50 mCi $mmol^{-1}$) was quantified by ion-exchange chromatography and scintillation spectrometry[15,16]. AChE activity is expressed in arbitrary units. In our standard assay conditions the hydrolysis of acetylcholine was inhibited by 80% with 5 μM BW 284C51 dibromide, a specific inhibitor of AChE activity. Catalase, used as a marker enzyme (11.3S), was determined colorimetrically[38] and proteins by the method of Lowry *et al.*[39]. The arrow represents the position of catalase.

nerves[30] do not possess this capacity. In addition, motor nerves can induce high sedimentation coefficient AChE, similar to the specific form of rat motor endplates, as has been reported for denervated muscle endplates[2], non-synaptic segments of skeletal muscles[2], original endplates in denervated muscles after reinnervation at a different site[25], primary cultures of rat muscle cells[37], and smooth muscle (this paper).

Aequorin luminescence during activation of single isolated smooth muscle cells

INCREASED cytoplasmic Ca^{2+} supposedly couples excitation to contraction in smooth muscle. But there have been no direct measurements of such an increase and there is little information about the kinetics of changes in intracellular Ca^{2+} during individual contractions of smooth muscle. Thus the basic aspects of excitation–contraction (EC) coupling in smooth muscle are not known with the same degree of certainty that exists for striated muscle[1]. For example, there is a long delay between stimulation and contraction in smooth muscle; this delay might result from a slow onset of Ca^{2+} release after a change in surface membrane potential or from the slowness of some other process[2]. If it were possible to correlate measurements of transmembrane potential, intracellular Ca^{2+} and contraction in the same single cell the mechanism of EC coupling in smooth muscle might be better understood. Some progress in this direction has been made by the development of methods for enzymatic isolation of smooth muscle cells and measuring electrical activity and force production or shortening in these single cells[2–6]. We report here a further approach to the problem by (1) microinjecting the Ca^{2+} indicator aequorin into smooth muscle and (2) directly measuring changes in intracellular Ca^{2+} during EC coupling in single isolated smooth muscle cells. Cytoplasmic Ca^{2+} evidently began to rise without detectable delay following a single electrical stimulus applied to a cell injected with aequorin and reached a peak well before contraction presumably began. The long delay, therefore, between stimulation and contraction seems inherent in the mechanism by which the contractile proteins of smooth muscle are activated.

All experiments were performed on single smooth muscle cells isolated from the stomach muscle of the toad, *Bufo marinus*, by an enzymatic digestion technique that involved the use of trypsin and collagenase. Isolated cells obtained by this technique exhibit physiological, pharmacological, metabolic and ultrastructural properties similar to those of cells in the isolated tissue[4–6]. But they do not exhibit slow rhythmic spontaneous potential changes once the nerve endings are removed[3].

Photomicrographs made during injection of a single smooth muscle cell are shown in Fig. 1. The pipette was left in the cell following the shortening that accompanied insertion. Small volumes of the aequorin solution were then injected by applying gaseous pressure to the butt end of the pipette. The relaxation that resulted when the injected liquid contained EGTA or EDTA was sustained until the cell was stimulated by a current pulse[7]. The swelling that indicated an injection of liquid rapidly subsided when the pressure was released. A cell could typically be injected several times without the swelling itself inducing contraction. The pipette was then withdrawn from a cell, removed from the bath, the quartz–iodine lamp was turned off, and a 25-mm diameter light guide, which extended to the shutter of a photomultiplier[8], was centred above the cell. Thus, stimulation occurred several minutes after injection whereas aequorin distribution in the cross-section of the injected segment was presumably uniform in only a few seconds (assuming a diffusion coefficient of aequorin of 5×10^{-8} cm^2 s^{-1} (ref. 8); the maximum diameter of 11 cells that were fixed when fully relaxed and subsequently measured by scanning electron microscopy was 4.34 ± 0.32 μm). Withdrawal of the pipette did not cause contraction (Fig. 1) and an electrical stimulus could elicit shortening and relaxation after the entire procedure that was not detectably different from a shortening response elicited before the procedure.

The pre-stimulus level of light emission from an aequorin-injected cell was not detectably different from the light recorded during stimulation of a non-injected cell (that is, there seemed to be no 'resting glow' and no change in anode current from the photomultiplier associated with the electrical stimuli themselves). But when a single electrical stimulus was applied to an injected cell a rapid rise in light output was observed. Light output reached a peak within about 10 ms of the onset of stimulation in Fig. 2 for example. The average (± s.e.m.) time to peak was 4.8 ± 0.6 ms in 27 of the cells. The response was sometimes large enough to saturate the recording system and the time to peak was not estimated in those cases. Light emission in Fig. 2 initially decayed as a single exponential with a rate constant of 37 s^{-1} but it was still above the pre-stimulus level until at least 250 ms after the onset of the stimulus. Therefore, the rise and most of the fall in luminescence was complete well before mechanical events presumably even began[2]. This is in striking contrast to the behaviour of amphibian skeletal muscle cells where the onset of force development lags no more than a few milliseconds behind the onset of light and light emission declines to only about half its peak level by the time peak force has developed[8].

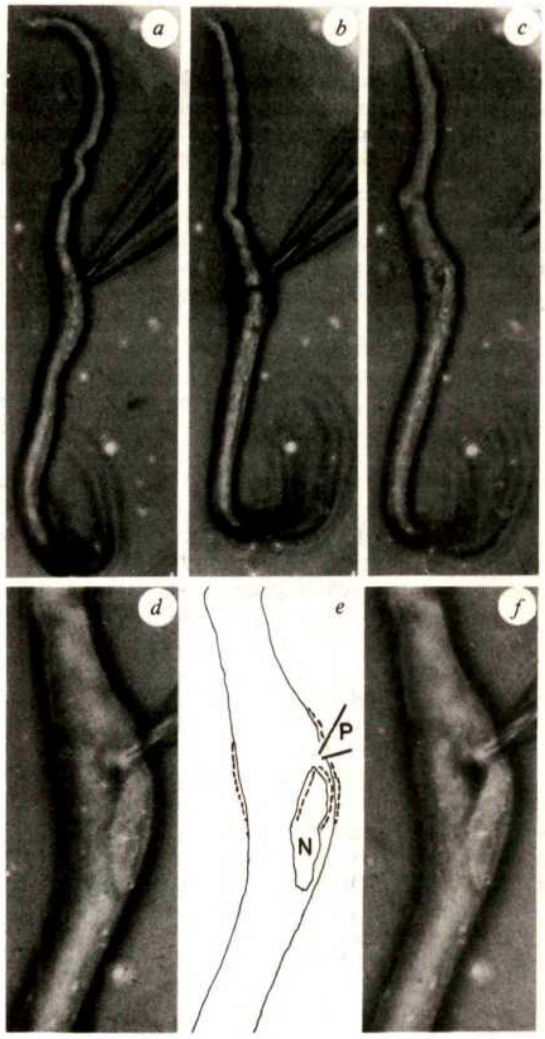

Fig. 1 Injection of aequorin into an isolated smooth muscle cell. Photomicrographs made from selected frames of a 16-mm cine film (12 frames per s) taken through an inverted microscope with a Zeiss ×40 phase contrast objective. *Upper row*: Magnification ×928. *a*, The cell before insertion of the micropipette containing aequorin; *b*, 5 s after the insertion of the micropipette; insertion triggered slight shortening of the cell probably caused by a momentary leakage of Ca^{2+} along a shunt resistance in parallel with the input impedance of the cell; *c*, 2 s after withdrawal of the micropipette. Twice between *b* and *c* pressure was applied briefly (~1 s) to the micropipette; liquid apparently entered the cell each time since each pressure pulse was accompanied by perceptible but evanescent swelling. The cell remained relaxed following withdrawal but when electrically stimulated it contracted. *Lower row*: Magnification ×1,740, *d*, The same cell after insertion of the micropipette but just before injection of liquid; *e*, the superimposed outlines of the cell before (continuous lines) and during (dashed lines) injection (that is, *d* set on *f*); *f*, during injection of aequorin. The micropipette (P) was always inserted into the uppermost part of the middle of a cell, and when liquid was injected the cine films showed that the most conspicuous distention was usually in a plane perpendicular to the page; furthermore, the nucleus (*N*) shifted during injection. We also recorded membrane potential responses to electrical stimulation from some isolated cells, and responses ranged from being slow and regenerative during long-duration pulses (see ref. 3) to fast and graded following short-duration pulses (Fig. 2). The entire range of responses could be obtained reproducibly from the same cell and showed that microinjection *per se* did not necessarily abolish the characteristic ability of these cells[3] to respond to depolarisation. We also photographed shortening and relaxation of injected cells[7], which was apparently unchanged and reproducible. This showed that microinjection *per se* did not necessarily change normal EC coupling in these cells. Aequorin was dissolved in either 33 mM EGTA (*p*H 7.0), 50 mM EDTA (*p*H 8.0), or quartz distilled water (*p*H 7.4). Chelating agents can influence aequorin results and their presence may be undesirable as a general rule[17]. But EDTA or EGTA in a micropipette prevented or reversed the tendency for a cell sometimes to shorten irreversibly during pipette insertion (Fig. 1). Thus a chelator was often present in our aequorin solutions (for example, the aequorin solutions used to obtain Figs 1 and 3 contained EDTA whereas the solution used to obtain Fig. 2 contained only quartz distilled water). Another advantage to the presence of EDTA or EGTA was that a buffer should oppose a change in $[Ca^{2+}]$ if it remained undiluted or did not become saturated with Ca^{2+} once inside the cell. Aequorin would then have either detected no change in Ca^{2+} or have indicated a delayed, slow rise as the buffer became saturated. On the contrary, we saw a rapid rise in light emission. Furthermore, the cells contracted and relaxed normally in response to punctate electrical stimulation delivered less than a minute after the injection of EDTA or EGTA which supports the idea that the chelators assume little functional importance after injection[7]. Aequorin solutions were put into filament containing glass micropipettes and pressure injected into individual cells by means similar to those already described for skeltal muscle[8]. But some of the differences in procedure were as follows: (1) the resistances of the micropipettes ranged from 15 to 50 MΩ when filled with 3 M KCl; (2) phase-contrast optics and a quartz–iodine lamp were used for both visual observations and cine-micrography; and (3) cells were stimulated either by a transverse electric field, or by the passage of current between 5 M NaCl in a blunt glass pipette next to a cell and a platinum wire anode positioned at the periphery of the liquid bath. In all the experiments reported here (34 cells) the cells were bathed in a high Ca^{2+} Ringer solution (about 30× normal) that contained (mM) calcium 57, potassium 3.0, magnesium 0.98, sodium 45, chloride 162, sulphate 0.98, Tris(hydroxymethyl)aminomethane 2 (*p*H 7.4), glucose 11, and 6 mg l^{-1} gentamycin. A high external $[Ca^{2+}]$ facilities microelectrode impalements[3] and does not change the delay between an electrical stimulus and the onset of contraction[2]. The temperature of the bath ranged from 25° to 34 °C.

The cause for the falling phase of an aequorin response is not certain, but several possibilities can probably be eliminated. First, the decay does not represent total depletion of aequorin since a second stimulus could induce a second flash of light after only one injection; furthermore, the rate constant for the decay of aequorin luminescence from the cells (for example, Fig. 2) was about 20 times higher than the rate constant for decay when aequorin is consumed *in vitro* by rapid mixing with a maximally effective concentration of Ca^{2+} (ref. 9). Second, the rate of quenching of luminescence when aequorin is exposed *in vitro* to Ca^{2+} chelating agents[9] is about five times higher than the rate constant for decay of light emission from these cells. Thus, the falling phase (Fig. 2) was not determined by the maximum rate imposed by the kinetics of the aequorin reaction. It is also unlikely that the fall of an aequorin response is caused by movement or by a change in the intrinsic optical properties of a cell because the maximum length changes or birefringence changes occur several thousand milliseconds after the maximum change in light emission following electrical stimulation[5,6]. Calcium binding to sites within the cell and/or the removal of Ca^{2+} from the cytoplasm by membrane associated reuptake mechanisms most likely account for the decay of light[1].

Luminescent responses were not always of the type shown in Fig. 2 (see for example, Fig. 3). This particular atypical response was much larger and more complex than the type in Fig. 2 and exhibited three phases. Other cells showed only the first phase (I), which could be reproduced by subsequent stimuli[10]. The second phase (II) had a rate of decay that was similar to the rate of decay of the response in Fig. 2. The final phase (III) decayed slowly and had a time course consistent with the overall consumption of aequorin[9]. Our hypothesis is that the first and last types of luminescent responses were not only atypical aequorin responses but were associated with atypical membrane responses, that is, responses different from those in Fig. 2 or in ref. 3. Atypical responses might be due to cell injury before or during a stimulus. For example, a cell segment or an entire cell can become inexcitable as a consequence of micropipette penetration or pressure injection yet undergo little or no significant decrease in resting potential[11–14]. An electrical stimulus, particularly an excessively intense stimulus, could change the membrane potential of such a cell and thus elicit a luminescent response. The total light emitted during responses of the last type (III) were largest and most readily detected but were probably associated with an atypically large rise in intracellular Ca^{2+}. Subsequent stimulation did not elicit further light emission which supports the idea that this type of response (III) is due to overall aequorin consumption. Successive stimuli applied to several such cells in a syncytium could elicit apparently reproducible responses but from different cells.

Observations obtained from single isolated cells preclude this last complexity.

Earlier studies left open the possibility that there might be a long delay between stimulation and the onset of intracellular Ca^{2+} release in smooth muscle[2]. But the rapid rises in light reported here suggest that the delay in EC coupling is not likely to be due to this possibility. Nor is it likely that the delay can be ascribed to the time for diffusion of Ca^{2+} through the cytoplasm. The small diameter of these cells should permit radial gradients in the intracellular $[Ca^{2+}]$ to be dissipated within 3 to 4 ms after the onset of a stimulus if diffusion is the major factor determining Ca^{2+} distribution. Calcium may carry the current producing a change in membrane potential in these cells[3]. Therefore, Ca^{2+} entry could account for part if not most of the aequorin signal. The source of the Ca^{2+} cannot be inferred from the present results alone. But one can now discount the possibility that the latency for contraction in smooth muscle results from a delay in the exposure of the contractile filaments to Ca^{2+}. Thus the rate limiting step seems to be imposed by a slow reaction during which the contractile proteins in smooth muscle are activated. Others have suggested that a sequence of Ca^{2+}-sensitive phosphorylation reactions are required for the activation of smooth muscle[15,16], and our results support the idea that these reactions impose the characteristically long delay in the activation of smooth muscle contraction.

We need more information to infer the sites responsible for both the rise and fall in intracellular Ca^{2+} following stimulation of these cells. But now that one can inject aequorin into smooth muscle cells these and other questions about the mechanism of EC coupling in smooth muscle can perhaps be answered.

This work was done during the tenure of a Research Career Development Award to F.S.F. (K4HL 00048) and an Established Investigatorship of the American Heart Association to SRT (74-188). F.S.F. was also supported by the Muscular Dystrophy Association. We thank F. G. Prendergast, J. J. Singer and J. V. Walsh for discussions.

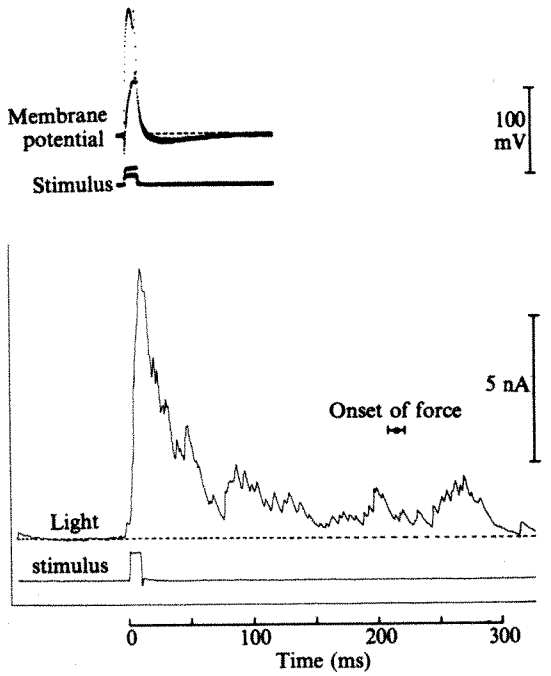

Fig. 2 Light emission and membrane potential change from single, isolated smooth muscle cells stimulated by 10-ms pulses. *Lower traces*: Light emission from a single cell following pressure micro-injection of aequorin and electrical stimulation. The aequorin response was initiated by a pulse applied via wires lying parallel to one another along either side of the cell[2]. The filled circle and bar labelled onset of force indicates the average delay (± s.e.m.) between a single electrical pulse and the first detectable sign of mechanical activity[2]. *Upper traces*: Membrane potentials recorded through the same microelectrode (filled with 3 M KCl) that was used to inject the stimulus current into the cell. Field stimulation, on the other hand, either distorted the membrane response recorded via a microelectrode or saturated the recording amplifier. The stimulus duration, solution composition, temperature, and other experimental conditions were the same as those used to obtain the lower aequorin traces.

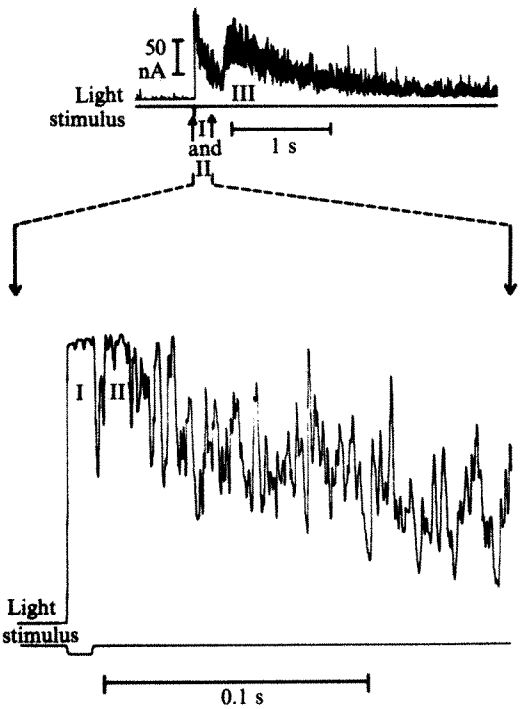

Fig. 3 An unusually large and complex light response from an isolated smooth muscle cell injected with aequorin and then stimulated by a single 10-ms pulse. The entire reponse is shown on the slower time scale (upper traces). The initial part of the same response is shown on a faster time scale in the lower traces. The initial rise and fall in light (I) is associated with the period of the stimulus. The second rise and fall in light (II) has a time course similar to the response shown in Fig. 2. The third rise and fall in light (III) is the slowest of the three, and has a time course consistent with the partial or total consumption of the aequorin in the cell[9].

Light-activated drug confirms a mechanism of ion channel blockade

A VARIETY of mechanisms underlie the pharmacological blockade of membrane excitability. Some drugs seem to reduce the frequency at which ion channels open; a good example is the effect of curare on acetylcholine receptor channels at normal resting potentials. Another sort of mechanism may account for the action of many local anaesthetics and related drugs containing charged ammonium groups. It is postulated that such molecules block transmembrane currents as they bind to sites within open ion channels, much like a plug in a drain, with the important difference that the events occur on a millisecond time scale. This model, which we shall call 'open-channel blockade', was first applied to the effect of internal tetraethylammonium ions on K^+ channels in squid axon[1] and more recently to similar actions of local anaesthetics on acetylcholine receptor channels[2–4] and on electrically excitable Na^+ channels[5]. (Curare seems to exert an additional open-channel blockade at high negative potentials[6,7].) The concept of open-channel blockade would receive direct experimental support from the demonstration that the blockade is exerted even if the blocking molecule is not bound to the channel (or indeed is not present at all) until after the channel opens. Such a demonstration is made possible by a drug that (1) blocks acetylcholine receptor channels in *Electrophorus* electroplaques and (2) is created, in less than a millisecond, by a flash of light.

Bieth *et al.*[8] have described the photoisomerisable compound, *N-p*-phenylazophenylcarbamylcholine iodide (EW-1, Fig. 1). The *cis* isomer can be formed from the *trans* isomer by exposure to light of wavelength 300–500 nm and spontaneously re-isomerises with a time constant of approximately 120 s at room temperature and neutral *p*H. A solution can be maintained in a predominantly *cis* state by steady exposure to 360-nm light. When *cis*-EW-1 is applied to the innervated face of a voltage-clamped *Electrophorus* electroplaque, neurally evoked postsynaptic currents (PSCs)[9–11] decay more rapidly than normal,

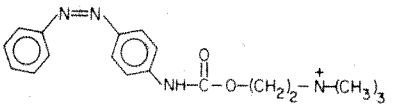

Fig. 1 *N-p*-phenylazophenylcarbamylcholine (EW-1), a light-activated cholinergic blocking drug.

the effect reaching fourfold at a concentration of 50 μM. *cis*-EW-1 also affects the response to bath-applied agonist, causing diminution of agonist-induced currents at equilibrium and rapid components in voltage-jump relaxations. For both PSCs and equilibrium agonist-induced currents, the blockade is more pronounced at more negative membrane potentials. Such effects typify the blockade of acetylcholine receptors by local anaesthetics and other suspected open-channel blockers[12–17]. Similar, but much weaker, effects are seen with *trans*-EW-1.

The light-flash experiments made use of the xenon flash tube and the optical system described by Nass *et al.*[18]; the flash was 90% complete within 0.5 ms (individual molecules probably isomerise within less than a microsecond after absorbing a photon). The preparation was bathed in *trans*-EW-1 and kept in the dark between flashes. In experiments on neurally evoked PSCs, a flash accelerated the decay phase of the PSC (Fig. 2). Very few channels open during the decay phase[19–22]; therefore the newly created *cis*-EW-1 molecules blocked channels that were already open. After the flash, the PSC decayed with at least two exponential components. We have quantitative data for only the fastest component, which accounted for more than half the decay amplitude in all conditions. This component's rate constant increases at higher flash intensities, suggesting that it arises from binding of newly created *cis*-EW-1 molecules. Furthermore, the increase is linearly proportional to the number of photoisomerisations (Fig. 3), as expected if each channel can be blocked by the binding of just one *cis*-EW-1 molecule.

Steady conductances are induced by bath-applied agonist. If EW-1 was present as well in the bathing solution, a flash produced a relaxation to a smaller conductance (Fig. 4). As in the PSC experiments, the light-flash relaxation had at least two exponential components. The amplitude of the fastest component was graded with the flash intensity and its rate

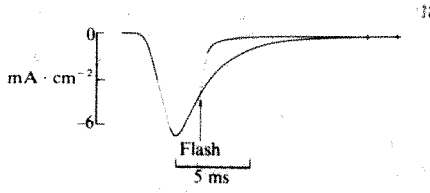

Fig. 2 A light-flash experiment with neurally evoked PSCs. Superimposed traces from two successive voltage-clamp episodes, at an interval of 0.3 s, in 10 μM *trans*-EW-1. During the second episode, a flash was delivered, isomerising at least 80% of the *trans*-EW-1 molecules to the *cis* isomer. Voltage −150 mV. Temperature 16 °C. Cell 57-42-T34.

constant was greater than that of a voltage-jump relaxation just before the flash, again showing that the blockade arises from an increased rate of channel termination rather than from a decreased rate of channel opening. As a percentage decrease of the conductance, the fast component had the relative size 1.0:0.6:0.35 for the agonists suberyldicholine, acetylcholine, and carbachol. (The experiments were carried out after pretreatment with methanesulphonyl fluoride to block acetylcholinesterase[10].) Thus, the initial component of the blockade is greater for agonists with a greater channel duration[10,23], as expected if the newly created *cis*-EW-1 molecules suddenly increase the rate constant for channel closing rate by a fixed amount (in ms^{-1}), with no dependence on the nature of the bound agonist.

The light-flash relaxations had a spectral dependence similar to that of the *trans* → *cis* photomerisation of EW-1. When the experiments were carried out using *cis*-EW-1 (rather than *trans*-EW-1), flashes had little additional effect. The signals are specific to acetylcholine receptor channels: light flashes have no effect on electrically excitable Na currents, even in the presence of EW-1.

There are interesting complications in these experiments. (1) The flash-induced blockade in a given *trans*-EW-1 solution is

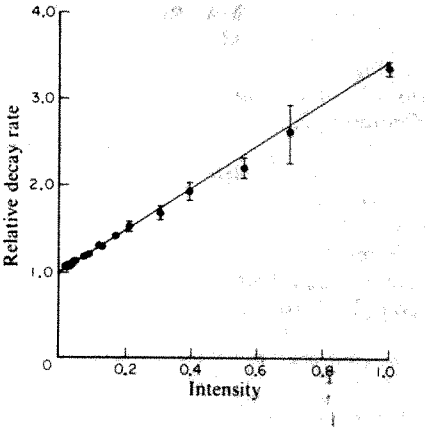

Fig. 3 PSC kinetics as a function of flash intensity. Data from trials like that of Fig. 3, in 5 μM EW-1. Vertical axis, rate constant of fastest PSC component after the flash, normalised to the value for the immediately preceding trial without a flash. Flash intensity was varied with neutral-density filters; intensity of 1.0 corresponds to 40% *trans* → *cis* photoisomerisation. Error bars show ±s.d. Temperature 10 °C. Cell 57-61, 62.

0028-0836/79/320509—02$01.00

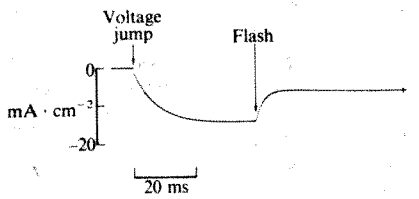

Fig. 4 Voltage-jump and light-flash relaxations in the presence of acetylcholine and 5 μM EW-1. Agonist-induced current is shown; passive and capacitative currents have been subtracted. Seven milliseconds after the start of the episode, the voltage was jumped from +50 to −150 mV. At about the midpoint of the episode, a flash was delivered, producing a conductance decrease. Flash intensity was the same as for the experiment of Fig. 2. Temperature 10 °C. Cell 61-72, T70, 71.

much greater than the steady-state blockade in a nearly pure *cis*-EW-1 solution of equal concentration. (2) Most of the blockade is transient, disappearing with a time constant of about 300 ms after the flash, even though *cis*-EW-1 has a lifetime of at least 40 s over the *p*H range from 2–13. These facts suggest that *trans*-EW-1 accumulates in the synaptic cleft; the flash would transiently produce a local *cis*-EW-1 concentration in excess of that in the bathing solution. The site of accumulation is probably not the catalytic site of acetylcholinesterase[8], because in experiments with carbachol, the light-flash relaxations did not change significantly after the enzyme was inactivated with diisopropyl fluorophosphate[9] or with methanesulphonyl fluoride[10]. The site of accumulation could be the peripheral anionic site of acetylcholinesterase[24], the acetylcholine receptors themselves, or some other component of the membrane or synaptic cleft. We do not know whether *cis*-EW-1 accumulates at the same site.

We have obtained very similar results using *N*-*p*-phenylazophenyl-*N*-methyl carbamylcholine and *N*-*p*-phenylazophenyl-*N*-phenyl carbamylcholine[25]. Like other experiments with light-activated compounds, these studies extend our knowledge of drug-receptor mechanisms[18,25,29]. With similar techniques it may be possible to test another interesting facet of the 'open-channel blockade' model, namely that the channel conducts again as the blocking drug leaves its binding site[4,16].

We thank D. Williams for performing the dissections, M. Walsh for help with the equipment, and J. Nerbonne for discussion. Occlusion of K ions in the unphosphorylated sodium pump

POST, Hegyvary and Kume[1] found that the rate of rephosphorylation of $(Na^+ + K^+)$ATPase that had just been dephosphorylated depended on which congener of K (Rb or Li) had been used to catalyse the hydrolysis of the phosphoenzyme, even when the experiments were done in such a way that the composition of the medium during the rephosphorylation was constant. To explain the ability of the enzyme to 'remember' which kind of ion had catalysed the hydrolysis, they postulated that during the hydrolysis the catalysing ions became occluded within the enzyme, and were released only later after a slow conformational change. Furthermore, as ATP in high concentrations accelerated the rephosphorylation, they supposed that the slow conformational change was accelerated by the binding of ATP to a low-affinity site on the enzyme. Karlish, Yates and I.M.G.[2] suggested that the hypothetical 'occluded-K form' of Post *et al.* was identical with the form of unphosphorylated $(Na^+ + K^+)$ATPase that predominates in K-containing Na-free media; they found that the conversion of that form (E_2K) into the form (E_1Na) that predominates in high-Na media was very slow ($k \approx 0.25\ s^{-1}$ at 20 °C), and was accelerated by nucleotides acting with a low affinity and without phosphorylation. Karlish *et al.* also studied the conformational change in the reverse direction—$E_1Na \rightarrow E_2K$—and concluded that K ions combine with the E_1 form of the enzyme at sites with a relatively low affinity. They therefore suggested that the occluded-K form could be generated either following the binding of K^+ ions at low-affinity sites, probably on the intracellular surface of the membrane, or by the hydrolysis of phosphoenzyme catalysed by K ions bound to high-affinity sites on the extracellular surface of the membrane[2,3] (see Fig. 1). They pointed out that, if their hypothesis were correct, it could account for inward and outward movements of K ions through the sodium pump, and could explain why orthophosphate and ATP (or its non-phosphorylating analogues) are required for K–K exchange. However, the similarities between the properties of the occluded-K form and the form that predominates in K-containing, Na-free media could be coincidental. Furthermore, the idea of an occluded-K form is also open to doubt, as the experiments of Post *et al.* prove only that the product of the hydrolysis of phosphoenzyme differs depending on whether Rb or Li ions catalyse the hydrolysis, not that the ions become trapped inside. Both problems could be resolved if it were possible to show that, in Na-free media, K ions or Rb ions binding to the unphosphorylated form of the enzyme were indeed occluded. We report here experiments showing that they are.

Briefly, the procedure followed in these experiments was (1) to suspend a partially purified suspension of $(Na^+ + K^+)$ATPase in a medium free of Na and Mg and containing 100 μM ^{86}RbCl, with or without nucleotide; (2) to pass the suspension rapidly down a cation-exchange column loaded with Na; (3) to measure

	2 mM ATP	0.572 ±0.018	0.351 ±0.025	—	—
	2 mM ADP	0.582 ±0.010	0.318 ±0.012	—	—

One-mg quantities of $(Na^+ + K^+)$ATPase (specific activity 12 μmol per mg per min), suspended in 0.5-ml portions of a medium containing 100 mM Tris/Tris Cl (*p*H 7.4 at 20 °C), 15 mM histidine, 1 mM EDTA (Tris salt) and 100 μM ^{86}RbCl, with or without nucleotide, were passed through columns of Biorad Biorex 70 carboxylic resin (50–100 mesh) in the Na form. Each column was prepared by putting the resin, suspended in 100 mM HEPES (Na salt, *p*H 7.4), in the barrel of a 1-ml disposable tuberculin syringe (cross-sectional area 0.17 cm^2) whose tip was loosely plugged with glass fibre and fitted with a nylon tap. The final bed volume was 0.5 ml, and the total capacity was 1.65 mEquiv. After the resin had packed down, the tap was opened until the surface of the Na HEPES solution reached the top of the resin. The upper part of the syringe was then filled with water, and acid-washed sand was allowed to settle through the water to form a layer 1 mm thick on top of the resin. This was to prevent contamination of the enzyme suspension with Na from the resin. The water above the sand was removed by aspiration, and the upper part of the syringe was washed twice with water. The enzyme suspension was slowly run into the syringe without disturbing the sand layer, and the syringe was mounted vertically on the moveable platform of a Palmer stand, whose coarse screw (pitch 5 mm) could be turned at predetermined rates by an electric motor acting through a friction clutch. The piston was inserted into the barrel so that about 0.25 ml of air was trapped above the enzyme suspension; a small hole drilled through the wall of the barrel, at a point corresponding to 1.3 ml on the (extrapolated) scale, allowed this to be done without any significant rise in pressure. The tap was opened and the motor switched on. Suitable stops had been arranged so that, as the syringe was raised by the motor, the piston was pushed in, the movement beginning only after the motor had reached its set speed, and terminating abruptly just before the piston reached the surface of the resin. The flow rate was 0.22 ml s^{-1} and the temperature 21 °C. The effluents were analysed for total protein[7] and for ^{86}Rb. The figures in the second and third columns of the table are each the mean of three determinations ±s.e.m.

* Calculated by subtracting the average of the Rb contents of the ATP and ADP samples from the average Rb content of the nucleotide-free samples.

the amounts of radioactivity and of protein emerging from the column. Rb was used rather than K, partly because ^{86}Rb has a more convenient half life than ^{42}K, and partly because the data of Post *et al.*[1] suggest that Rb is released from the occluded form slightly more slowly than K.

Details of the procedure are given in Table 1, but it is convenient to consider some of them here. The main difficulty was to find conditions which allowed the column to remove free Rb from the suspension completely enough for the small amount of Rb occluded within the enzyme not to be masked, and quickly enough for the enzyme to emerge before too much of the occluded Rb had been released. $(Na^+ + K^+)$ATPase from pig kidney outer medulla was used because it can be prepared conveniently about 30% pure in reasonably large quantities[4], and the purified preparation is not vesiculate. When the suspending media were to contain ATP, the ATP was added only 1 or 2 min before the experiment, so that hydrolysis (in the absence of Mg and Na, and in the presence of 1 mM EDTA) should have been negligible. With 100 μM Rb, 2 mM ATP or ADP is more than sufficient to displace the equilibrium between E_2 and E_1 forms of the enzyme virtually completely in favour of the E_1 form[5]; in the presence of nucleotide, any occluded Rb would therefore have been released before the enzyme was added to the column.

Preliminary experiments showed that, with the conditions chosen: (1) in the absence of enzyme, the column removed more than 99% of ^{86}Rb from 0.5 ml of a solution containing 100 μM ^{86}RbCl, 100 mM Tris/Tris Cl (*p*H 7.4) and 1 mM EDTA (Tris salt); the small fraction of Rb remaining in the effluent was not significantly affected if the solution also contained 2 mM ATP; (2) when 1 mg of enzyme was added to the solution, 60 ± 4% of the enzyme was recovered in the effluent; the presence of 2 mM ATP did not significantly affect the recovery of enzyme.

The results of two separate experiments, each carried out in triplicate, are summarised in Table 1. In the presence of nucleotides the amounts of Rb that emerged from the columns were about 0.6% of the total, and not significantly different from the amounts of Rb that emerged from the columns in control experiments without enzyme. In the absence of nucleotides, an extra amount of Rb was carried through the columns, which is just what we should expect if the enzyme contained occluded

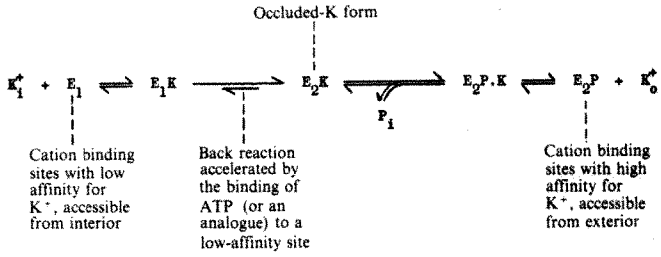

Fig. 1 Scheme showing the hypothesis of Karlish, Yates and I.M.G.[2], in which two routes to the occluded-K form are coupled back-to-back to produce a chain of reactions capable of carrying K ions through the membrane. Note: (1) E_2P in this scheme is identical with E_2P in the Albers–Post scheme (see Fig. 1 of ref. 8); E_2K in this scheme is identical with E_2K in Fig. 4 of ref. 2, and also with $E_2(K)$ in Fig. 5 of ref. 2 and Fig. 1 of ref. 8. (2) In the present experiments we are concerned only with the unphosphorylated forms of the enzyme. (When ATP was present, phosphorylation was prevented by the lack of Mg and, for most of the time, also of Na.)

Rb. Before we accept that explanation, however, we must see how this extra amount compares with the amount of occluded Rb that the enzyme might be expected to carry through the columns.

In the last column of Table 1, the extra Rb that appeared in the effluents in the absence of nucleotide has been expressed as nmol Rb per mg protein in each effluent. The specific activity of the enzyme used in these experiments was 12 μmol per mg protein per min, at 37 °C in standard conditions, and as enzyme approaching 100% purity has a specific activity of 40 μmol per mg protein per min in identical conditions, the purity of our enzyme must have been about 30%. If the molecular weight of the enzyme is assumed to be 250,000, our preparation must have contained 1.2 nmol of enzyme per mg protein. If each enzyme molecule can occlude two Rb ions, the maximum amount of occluded Rb would therefore be 2.4 nmol per mg protein. The amount of extra Rb to be expected in the column effluents is, however, less than this for two reasons: first, at an Rb concentration of 100 μM, not all the enzyme would have been in the E_2 form initially, and second, some of the occluded Rb would have been released during the time the enzyme was passing down the column. The relevant data for Rb are not available, but if we assume that Rb behaves like K, the fraction of enzyme in the E_2 form initially would have been about two-thirds[6]. The rate constant for the conversion of E_2K to E_1K, which is thought to be the rate-limiting step for the release of occluded K, has

been estimated to be about 0.25 s^{-1} at 20 °C in the absence of nucleotides[2,4]. Using the data in Table 1 of ref. 1, we calculate that the rate constant for the conversion of E_2Rb to E_1Rb is probably about 0.64 times as great. The amount of extra Rb to be expected per mg protein in the effluent is therefore $2.4 \times 0.67 \times \exp(-0.25 \times 0.64t)$ nmol, where t is the average time that enzyme in the effluent has spent passing through the resin. We cannot give a precise value for t, but it was almost certainly between 0.8 and 2.0 s. The expected amount of extra Rb is therefore between 1.17 and 1.41 nmol per mg protein. Given the uncertainties in the calculation, and the experimental errors, the agreement between the predicted and the observed values is remarkably good. We therefore conclude that the extra Rb carried through the columns with the enzyme in the absence of nucleotides does represent Rb occluded within the E_2 form of the enzyme.

We are now trying to adapt the rapid ion-exchange technique used in the above experiments to test the hypothesis[2,3] that Na ions are occluded within the phosphorylated $(Na^+ + K^+)$ATPase when it is in the E_1P conformation, the conformation believed to be the immediate product of phosphorylation of the protein by ATP.

We thank Mr R. H. Cook and Mr W. Smith for technical assistance and the MRC for financial support.

Highly active cyclic and bicyclic somatostatin analogues of reduced ring size

THE biological activity of an organic compound represents the sum of several properties, including solubility, absorption, transport, plasma protein binding, metabolism and receptor binding. The degree of molecular flexibility may affect these properties in different ways. Our approach to the design of somatostatin analogues with reduced susceptibility to metabolic inactivation has been both to eliminate those amino acids which are not required for biological activity and to increase the rigidity of the molecule. We report here the preparation of conformationally constrained analogues of somatostatin (Fig. 1, II*a* and III) which are highly active inhibitors of the release of insulin, glucagon and growth hormone *in vivo*. Analogue III (Fig. 1), which retains only four of the amino acids of the natural hormone (sequence 7–10), is relatively resistant to the action of trypsin *in vitro*.

We have already reported[1] the preparation of analogue I, a highly active bicyclic analogue of somatostatin that has a covalent bridge between the β-carbons of amino acids 5 and 12 (numbers assigned to amino acid residues of the analogues correspond to those of somatostatin). On the basis of the high biological activity of analogue I, we concluded that the corresponding β-carbons in somatostatin are in close proximity when somatostatin is bound to the receptors involved in the inhibition of the release of insulin, glucagon and growth hormone. Reduction of the disulphide bridge to give the monocyclic, dihydro derivative did not explain the high activity of analogue I *in vitro* and *in vivo*[1]. At that time our attention was focused on amino acids 7–10 of somatostatin. These are important in the interaction with receptors whereas amino acids 5, 6, 11 and 12 are not. It had been reported earlier that amino acids 4 and 13 could be deleted individually while retaining biological activity[2]. These observations suggested that the amino acids to the left of the disulphide bridge of analogue I could be deleted and the disulphide bridge replaced by methylene groups while retaining biological activity. We synthesised analogue II*a*, cyclo-(Aha-Phe-Phe-D-Trp-Lys-Thr-Phe), also designed as an analogue of I incapable of *in vivo* reduction[3,4] (Aha is ω-aminoheptanoic acid). A disulphide-containing analogue of ring size similar to that of analogue II*a* has been reported to have significant biological activity[5].

The minimum requirements for biological activity can be tested further by replacing phenylalanines 6 and 11 of analogue II*a* by cystine, as we have reported for an analogue with the full ring size of somatostatin[1]. Therefore, we also synthesised the bicyclic analogue III, cyclo-(Aha-Cys-Phe-D-Trp-Lys-Thr-Cys), which retains only amino acids 7–10 of somatostatin.

These analogues were prepared as outlined in Fig. 2. The L-Trp analogue of II*a*, cyclo-(Aha-Phe-Phe-Trp-Lys-Thr-Phe) (II*c*), was prepared in a similar way. Analytical results and physical properties are summarised in Table 1. The NMR spectra at 300 MHz supported the structures by demonstrating

Table 1 Characterisation data for analogues

NH_4OH. ‖ When Thr (or Ser) precede cysteine in a peptide we have observed simultaneous destruction of both amino acids. Racemisation of Ile in the sequence Ile-Cys has been reported to involve thiazoline formation[10]. Presumably, thiazoline formation would allow further reactions when a β-hydroxyl, capable of elimination, is present. ¶ Determined by UV. # after 20 hours 6M HCl hydrolysis at 110 °C.

Table 2 Inhibition of release (relative potency of somatostatin = 1)

Compound	Glucagon	Insulin	Growth hormone *In vitro*	Growth hormone *In vivo*	Gastric secretion
I	1.4 (0.26–12.40)	1.53 (0.92–2.66)	0.37 (0.29–0.48)	1.88 (0.35–8.33)	0.10
II*a*	0.86 (0.44–1.53)	0.88 (0.30–2.45)	0.93 (0.69–1.2)	0.65 (0.20–4.61)	0.03
II*b*		0.020 (0.003–0.060)	0.03 (0.02–0.04)	0.14 (0.05–0.29)	0.03
II*c*	0.041 (0.004–0.150)	0.10 (0.05–0.19)	0.14 (0.12–0.16)	—	<0.01
III	2.66 (1.32–6.10)	3.50 (2.31–6.38)	1.24 (0.81–1.88)	2.55 (0.99–11.1)	0.05

The biological effects were measured using methods described previously[1]. Inhibition of glucagon and insulin release was measured in urethane anaesthetised rats. Growth hormone release inhibition *in vivo* was measured in pentobarbital-treated rats. *In vitro* inhibition of growth hormone release was measured using dispersed pituitary cells. Inhibition of gastric secretion was measured in dogs stimulated by pentagastrin. 95% confidence limits are given in parentheses. For glucagon release by analogue II*b*, a low level of activity was observed, with no dose response.

0028–0836/79/320512—03$01.00

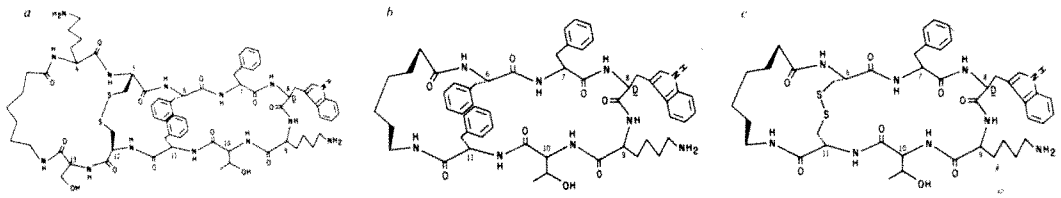

Fig. 1 Structure of analogues I, II*a* and III.

normal resonances for all the amino acids, with no unassignable resonances. The only abnormal resonance was the γ-CH_2 of Lys 9, shifted upfield about 1 p.p.m. in analogues II*a*, II*b* and III, a shift we have attributed to a proximity of the side chains of Trp 8 and Lys 9 in analogues with D-Trp in position 8. The high field resonance in these new analogues lacking Lys 4 permits unequivocal assignment to the CH_2 of Lys 9 as previously proposed[6].

The biological potencies of the analogues are summarised in Table 2, with the results previously reported for analogue I. In these respects analogues I, II*a* and somatostatin are nearly the same except that I and II*a* are less potent inhibitors of gastric secretion. It is clear from these and previous studies[1] that inhibition of gastric secretion involves unique structural requirements. The high potency of analogue II*a* provides additional evidence that *in vivo* disulphide reduction is not a prerequisite for the biological activity of analogue I.

We have suggested that the roles of Phe 6 and Phe 11 are related, at least in part, to stabilising a peptide conformation through the formation of a hydrophobic bond[1]. This conclusion is further strengthened by the high biological activity of analogue III relative to II*b*. The disulphide bridge of analogue III seems to be a prerequisite of high biological potency because the lack of bonding between amino acids 6 and 11, either covalent (III) or hydrophobic (II*a*), results in lowered potency, as seen in analogue II*b*. Once again, the D-Trp 8 analogue II*a* is more potent than the L-Trp diastereomer (II*c*), as was first observed with somatostatin[7] and later reported also in the dicarba-series[8]. We have interpreted this higher potency in the D-Trp series as representing a stabilisation of the biologically active conformation[6]. The high activity of analogues II*a* and III indicates that the binding of somatostatin to receptors is due chiefly to amino acids 7–10. The potencies reported in Table 2 not only reflect changes in receptor binding but are also a summation of *in vivo* effects, including metabolism. The *in vitro* growth hormone release data give the closest estimation of receptor binding because potential metabolism has been minimised by the use of conditions previously developed for a successful pituitary receptor model[9].

The bicyclic analogue III was more resistant to enzymatic cleavage, as demonstrated by its relative resistance to trypsin hydrolysis between lysine and threonine *in vitro*. The monocyclic analogue II*a* was cleaved by trypsin at about 100 times the rate of hydrolysis of III in identical conditions (1.5×10^{-3}M peptide). The course of hydrolysis was followed using high pressure liquid chromatography (HPLC) to assess the ratio of substrate to product at various intervals. It is interesting that in the presence of 1.5×10^{-3}M mercaptoethanol, analogue III was hydrolysed at about the same rate as II*a*. Thus, the disulphide bond adds enzymatic stability apparently through conformational or steric constraint. The lower rate of tryptic hydrolysis was due to reduced binding to trypsin because analogue III did not inhibit tryptic hydrolysis of II*a* even when present in a concentration 10-fold higher than that of analogue II*a*. The introduction of conformational constraint seems mainly to have increased K_M rather than prevented some needed conformational change along the pathway of hydrolysis.

There was an increased duration of action after subcutaneous administration of analogue III relative to II*a* and somatostatin (Fig. 3): the data in Fig. 3 show that 75 min after injection, both II*a* and III significantly inhibit the release of growth hormone, whereas somatostatin does not. At 135 min after injection, only analogue III shows significant inhibition of growth hormone release. Indeed, III significantly inhibited growth hormone release in this system up to 5 h after subcutaneous administration (to be reported in detail elsewhere). Although it seems reasonable that the greater duration of action is a consequence of the enhanced enzymatic stability of analogue III, it may be related in part to solubility differences, giving effectively depot forms of the analogue[8].

In conclusion, we believe that amino acids 7–10 of somatostatin, when constrained in the correct conformation, contain receptor binding elements sufficient to express the total activity of somatostatin for suppression of the release of insulin, glucagon and growth hormone. Our studies suggest that conformationally constrained structures can be designed to

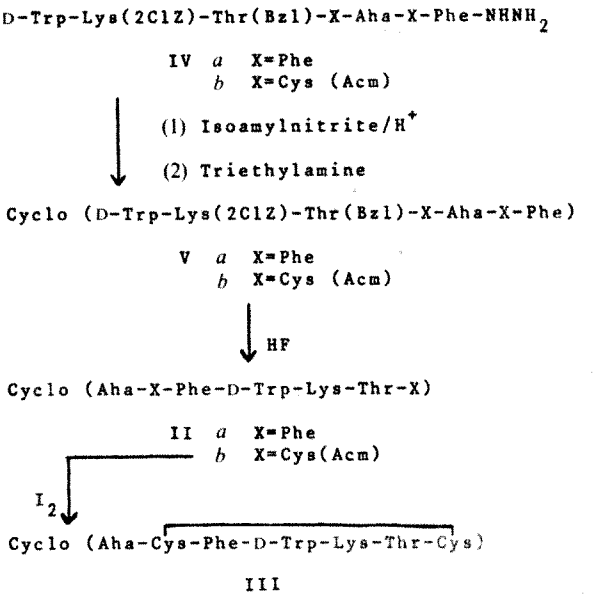

Fig. 2 Route for synthesis of analogues. The experimental details of the synthetic procedure are described in ref. 1 for larger ring monocyclic and bicyclic analogues of somatostatin. II*a* was prepared without purification of intermediates. The final product (III) was purified by chromatography on silica 60 using CH_2Cl_2/isopropanol/NH_4OH (concentrated) (60:40:5) as eluant. Isolated yield was 42% of product plus 22% of material showing trace impurities (melting point 234–236). In this study I_2 oxidation of analogue II*b* was carried out at a concentration of 3.2 mM in dimethylformamide using 6 equivalents of I_2. Excess I_2 was removed by filtration through silica gel 60, the I_2 being eluted with $CHCl_3$ and 10% MeOH/$CHCl_3$ while the peptide was adsorbed. III was eluted with $CHCl_3$/MeOH/H_2O (6:4:1) and the crude peptide product further purified by filtration through Sephadex G-50F, 50% AcOH, to give an isolated yield of 35%. III was generally prepared without purification of any intermediates. Purified samples of the intermediate II*b* were obtained by chromatography on silica gel, eluted with $CHCl_3$/MeOH/NH_4OH (70:30:3) followed by filtration through Sephadex G-25F (2M AcOH). The properties and analytical data obtained on these synthetic products and cyclo-(Aha-Phe-Phe-Trp-Lys-Thr-Phe) (II*c*) are summarised in Table 1. Final products had a purity of ≥98% as analysed by TLC and HPLC.

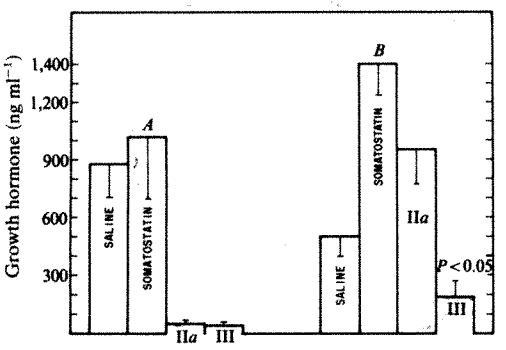

Fig. 3 Duration of action of somatostatin and analogues on the inhibition of growth hormone release. Male Sprague–Dawley rats (190–200 g) were injected with saline or compound subcutaneously. After 1 or 2 h sodium pentobarbital (17 mg per kg intravenously) was injected. The rats were bled 15 min later from the orbital sinus. The plasma was collected and assayed for growth hormone content by radioimmunoassay. The data are presented as the mean ± s.e.m. (six rats per group). Doses of somatostatin (50 μg) and analogues II*a* (50 μg) and III (25 μg) were chosen to attain equipotence. *A*, 75 min after administration; *B*, 135 min after administration.

decrease susceptibility to metabolism while retaining biological activity. Because analogue III shows greater stability both *in vivo* and *in vitro*, we believe that the incorporation of conformational constraint is a viable approach to the design of long acting somatostatin analogues.

δ-Aminolaevulinic acid is a potent agonist for GABA autoreceptors

ACUTE attacks of the hereditary hepatic porphyrias are frequently accompanied by neuropsychiatric symptoms. The presentation of nervous system involvement varies; in decreasing order of frequency, there may be motor neuropathy, confusion, psychiatric manifestations, hyperexcitability and epileptic-type seizures[1]. Psychiatric manifestations include depression, anxiety, insomnia and an organic brain syndrome[2]. Although the aetiology of the neural dysfunction in the acute attack is unknown, several mechanisms have been suggested at a neurochemical level. It is possible that porphyrin precursors, which are produced in excess by the liver during acute episodes, gain access to the nervous system and exert direct neurotoxic effects[3–5]; alternatively, a metabolic defect in haem biosynthesis in nerve cells might result in a functional haemoprotein deficiency which becomes critical at the time of the acute attack[6]. The porphyrin precursor, δ-aminolaevulinic acid (δ-ALA), exhibits various effects in mammalian central nervous tissue preparations. It inhibits high-affinity uptake and increases efflux of γ-aminobutyric acid (GABA)[3] and L-glutamate[4] in rat cortical synaptosomes; it also inhibits the $(Na^+ + K^+)$ ATPase isolated from rabbit brain and red blood cells[7]. These effects occur only at relatively high concentrations of δ-ALA (at least 10^{-4}M), and it is very unlikely that such concentrations are reached in the brain during acute porphyric attacks[8]. Recently, there has been strong evidence that release of GABA is subject to negative feedback control through presynaptic receptors on GABAergic terminals[9–11]. Here we report that δ-ALA inhibits potassium-stimulated release of GABA from preloaded synaptosomes, probably by acting as an agonist at these presynaptic receptors. This effect is evident at concentrations of δ-ALA (10^{-6}M) which are well within levels recorded in the cerebrospinal fluid of porphyric patients showing neuropsychiatric symptomatology[12].

The method used has been published previously[13]. Briefly, fresh synaptosomes prepared from the cerebral cortices of adult male Wistar rats were resuspended in 0.32 M glucose to give a protein concentration of about 5 mg ml^{-1} and diluted 1:10 with ice-cold incubation medium (final concentrations: 128 mM NaCl; 5 mM KCl; 2.7 mM $CaCl_2$; 1.2 mM $MgSO_4$; 0.1 mM aminooxyacetic acid to prevent GABA catabolism; 10 mM Tris-HCl buffer at *p*H 7.35). One-ml aliquots of the suspension were preincubated at 37 °C for 15 min in a water bath in an air atmosphere. [2,3−^{3}H]GABA of specific activity 54 Ci mmol^{-1} (Radiochemical Centre) was diluted with unlabelled GABA to give a specific activity of 10 Ci mmol^{-1} and a small volume (1/100 of the final volume) added to the incubation tubes to a final concentration of 0.5×10^{-6} M. Incubation was continued for a further 10 min after which the synaptosome suspensions were layered on Millipore filters (0.45 μm pore) resting on filter supports constituting the bottoms of four parallel superfusion chambers[14], and thermostatically maintained at 37 °C. The chambers were connected to a multichannel peristaltic pump, the excess medium drawn off at maximum flow rate and the filters washed with 10 ml of medium (concentrations as described above) containing 30 mM glucose. The flow rate was adjusted to 0.5 ml min^{-1} and 1-min fractions were collected directly into scintillation counting vials. Superfusion was continued for 10 min with plain medium to establish a

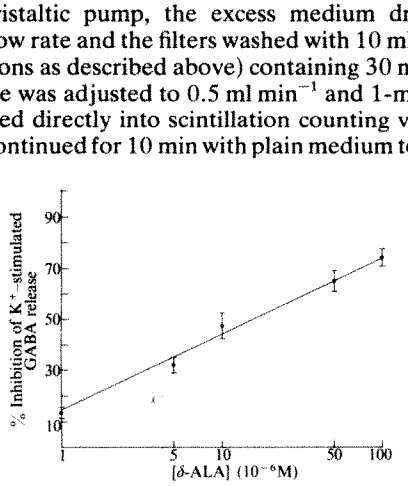

Fig. 1 A dose–response curve for the inhibition of potassium-induced GABA release by δ-ALA. The horizontal axis gives concentration of δ-ALA ($\times 10^{-6}$ M) on a logarithmic scale. Represented on the vertical axis is the % inhibition of potassium-stimulated (55 mM) GABA release. Each point is the mean % inhibition ± s.e.m. ($n = 4$). The curve is the best fit to the data by the method of least squares ($r^2 = 0.97$). It was not possible to produce 100% inhibition of the stimulated release as δ-ALA alone at concentration $>10^{-4}$ M caused increased efflux of radioactivity from the synaptosomes[3].

Table 1 Drug effects on the potassium-stimulated release of GABA from preloaded synaptosomes

Drug present	Induced release (% increase over baseline control)	Mean drug effect on induced release
55 mK K^+ alone (6)	188 ± 26.9*	
10^{-4} M δ-ALA alone (4)	23 ± 9.9	
55 mM K^+ 10^{-4} M δ-ALA (4)	48 ± 6.4†	−74.5%
55 mM K^+ + 10^{-4}M δ-ALA + 10^{-6} M bicuculline (4)	191 ± 13.2	+1.6%
55 mM K^+ + 10^{-5} M δ-ALA (4)	92 ± 13.5†	−51.1%
55 mM K^+ + 10^{-5} M δ-ALA + 10^{-6} M picrotoxin (4)	187 ± 10.2	−0.5%
55 mM K^+ + 10^{-6}M δ-ALA (4)	163 ± 7.5‡†	−13.0%
55 mM K^+ + 10^{-6}Mδ-ALA + 10^{-6} M bicuculline (4)	197 ± 13.1	+4.8%

Experiments were carried out as described in the text. The values in parentheses indicate the number of times the experimental conditions in the first column were repeated. Baseline efflux was calculated as % total tissue stores released per fraction (0.57 ± 0.068%, $n = 7$). The second column refers to the % increase in efflux over this control baseline level; in each case the mean ± s.e.m. is given. Statistical significance was calculated using the two-sided Student t-test. The third column represents the average drug-induced change compared with the release caused by 55 mM potassium alone. δ-ALA at concentrations $<10^{-4}$M had no effect on the basal release of radioactivity from the synaptosomes. Bicuculline and picrotoxin alone (10^{-6} M or 10^{-5} M) did not facilitate the release of GABA, presumably because the flow of superfusion fluid removed any GABA as it was released. In the absence of negative feedback effects to antagonise, the GABA receptor anagonists has no effect on basal efflux.

* Substitution of Mg^{2+} for Ca^{2+} in the medium did not significantly affect basal release of radioactivity, although 76 ± 2.2% ($n = 4$) of the K^+ (55 mM) induced release was Ca^{2+} dependent.

† $P < 0.001$, significant difference from 55 mM K^+ alone.

‡ $P < 0.05$, significant difference from 55 mM K^+ alone.

baseline rate of GABA efflux; the plain medium was then exchanged for the test medium containing the drugs listed in Table 1 and superfusion continued for a further 15 min. Aquagel I liquid scintillant, 5 ml, was added to each vial and the radioactivity of the vials was counted in a Packard Tri-Carb spectrometer at 37% efficiency. Filters were solubilised in 10 ml of Aquagel I and counted similarly. Stimulation of GABA release was calculated as the percentage increase in efflux over the baseline unstimulated level. The data obtained were analysed using a two-sided Student t-test and the results are shown in Table 1.

δ-ALA dose dependently reduced the potassium depolarisation-induced release of GABA from the nerve endings (Fig. 1). The reduction was significant at a δ-ALA concentration of 10^{-6} M, and at a concentration of 10^{-4} M 75% of the stimulated release was abolished. The concentration of δ-ALA which inhibited 50% of the potassium-stimulated release was approximately 10^{-5} M. In all cases the reduction was prevented by the GABA receptor antagonists bicuculline or picrotoxin (10^{-6} M) (Table 1). δ-ALA at 10^{-6} M or 10^{-5} M exhibited no effects on the basal release of GABA although, at 10^{-4} M, GABA efflux was slightly stimulated (Table 1). Neither bicuculline nor picrotoxin alone (10^{-6} M or 10^{-5} M) modified the basal release of radioactivity in the conditions used here. This is expected, as we consider that any GABA released from the tissue is rapidly removed from the superfusion chamber by the flow of medium. The concentration of GABA in the medium does not therefore reach the levels necessary to stimulate presynaptic receptors and hence the bicuculline or picrotoxin has no negative feedback effects to antagonise.

The evidence presented shows that δ-ALA, an ω-amino acid with a five-carbon chain similar in structure to GABA, reduces the amount of radioactivity released as a result of potassium stimulation, and that this effect is prevented by the GABA receptor antagonists bicuculline and picrotoxin. This is consistent with the idea that δ-ALA acts as an agonist at presynaptic receptors in the mammalian central nervous system. Indeed, it seems to be a fairly powerful agonist, inhibiting 50% of the stimulated release at a concentration of 10^{-5} M.

Although the influx of δ-ALA into the brain is limited[8], it has been demonstrated that δ-ALA can penetrate the blood–brain barrier of the rat at plasma concentrations known to occur in acute intermittent porphyria and appear in the cerebrospinal fluid in micromolar concentrations[15]. In addition, cerebrospinal fluid levels of $1.6–2.0 \times 10^{-5}$ M have been recorded in patients during acute attacks characterised by hyperexcitability and convulsions[12]. Our findings strongly support a direct mechanism whereby δ-ALA acts to inhibit GABA release from inhibitory nerve endings. This effect is evident *in vitro* at concentrations as low as and lower than those already recorded in the central nervous system during acute porphyric episodes.

Correlation of local stability of DNA during melting with environmental conditions

DNA MELTING studies have revealed fine structural features in the melting profiles of many natural DNAs[1–4]. Restriction fragments have been used to assign modes showing up in melting profiles to the denaturation of well delineated segments inside the DNA molecule[1,3] and possible correlations of these segments with biological functions have been suggested[1,5,6]. However, when the exact sequence of natural DNAs became available, known genetic or regulatory features extending over tens to hundreds of base pairs did not appear to be characterized systematically by simple physical parameters. For example, the base pair composition fluctuation of ΦX174 DNA is almost smooth[6,7], whereas several distinct modes are seen in experimental melting profiles[8,9], each reflecting separate melting of segments of hundreds of base pairs. Attempts have been made to calculate the melting profiles of DNA from its sequence[10–13], and two calculated melting profiles have been published for ΦX174 DNA. Both calculated curves show fine structure, but comparison with the experimental profiles showed 'no obvious

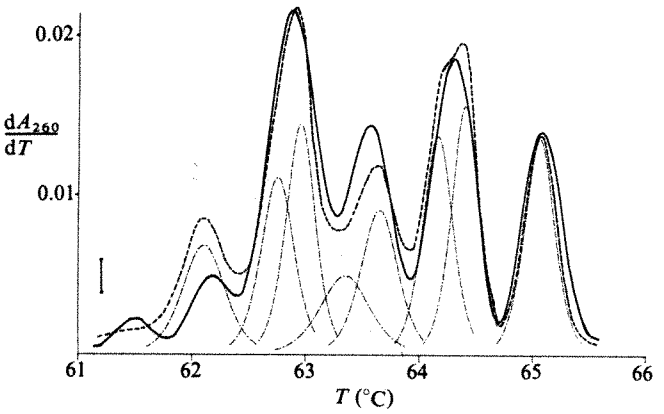

Fig. 1 Melting profile of a restriction fragment of SV40 DNA, extending from base pair 1,967 to 3,409 (origin: *Eco*RI restriction site). Solid line : experimental melting profile, obtained in 10 mm Na^+ (citrate), 10^{-4} EDTA; temperature incremented stepwise by 0.05 °C, mean heating rate 4 °C per h (see ref. 1 for experimental setup and procedure, and ref. 19 for data processing). Dashed line: calculated melting curve, for the sequence published by Fiers *et al.*[20]. Parameters used: $T_{AT} = 44.8$ °C, $T_{GC} = 93.9$ °C, $W = 4.07$, $b = 1.114$ (loop entropy factor), $\beta = 0.034$ (mode form factor); see text and refs 14 and 16 for definition of these parameters. Dashed-dotted curves correspond to the melting profiles of individual, cooperatively melting segments (only segments with 100 or more base pairs are shown).

systematic relationship' (ref. 8). The very different profiles observed for the same ΦX174 DNA in two different ionic strengths[8] could not be accounted for by the theory used. Thus the melting profile is not determined by the DNA sequence alone. However, recently good agreement between the calculated and experimental melting profile of ΦX174 DNA was obtained by Azbel[14–16]. Azbel's model is based on the observation that nucleation of the helix–coil transition requires much higher energies than that exchanged between base pairs, so that behaviour of DNA is mainly correlated to its ground state at a given temperature inside the melting range (see ref. 16). We have applied Azbel's model to another DNA of known sequence (a restriction fragment of SV40 DNA) and ΦX174 DNA in two different environmental conditions, and we obtained good agreement between predictions and experimental observations.

It can be seen from Figs 1 and 2*b*, *c* that the agreement between calculated melting profiles and experimental curves, obtained in this laboratory or published by Vizard *et al.*[8], is satisfactory both in terms of the number of modes and the shapes of the various profiles. Minor differences (most are within the experimental error bar) may be due to linear, first order approximation to Azbel's model.

An interesting aspect of the model is the fact that a phase-diagram can be constructed to show the variation of the ground state as a function of two dimensionless parameters which are related to standard thermodynamic functions. The phase diagram shown in Fig. 2*a* predicts the state of ΦX174 DNA, inside its melting range, for a range of $W = V/(f_1 - f_0)$, where V is the boundary energy between helix and coil regions, and $f_1 - f_0$

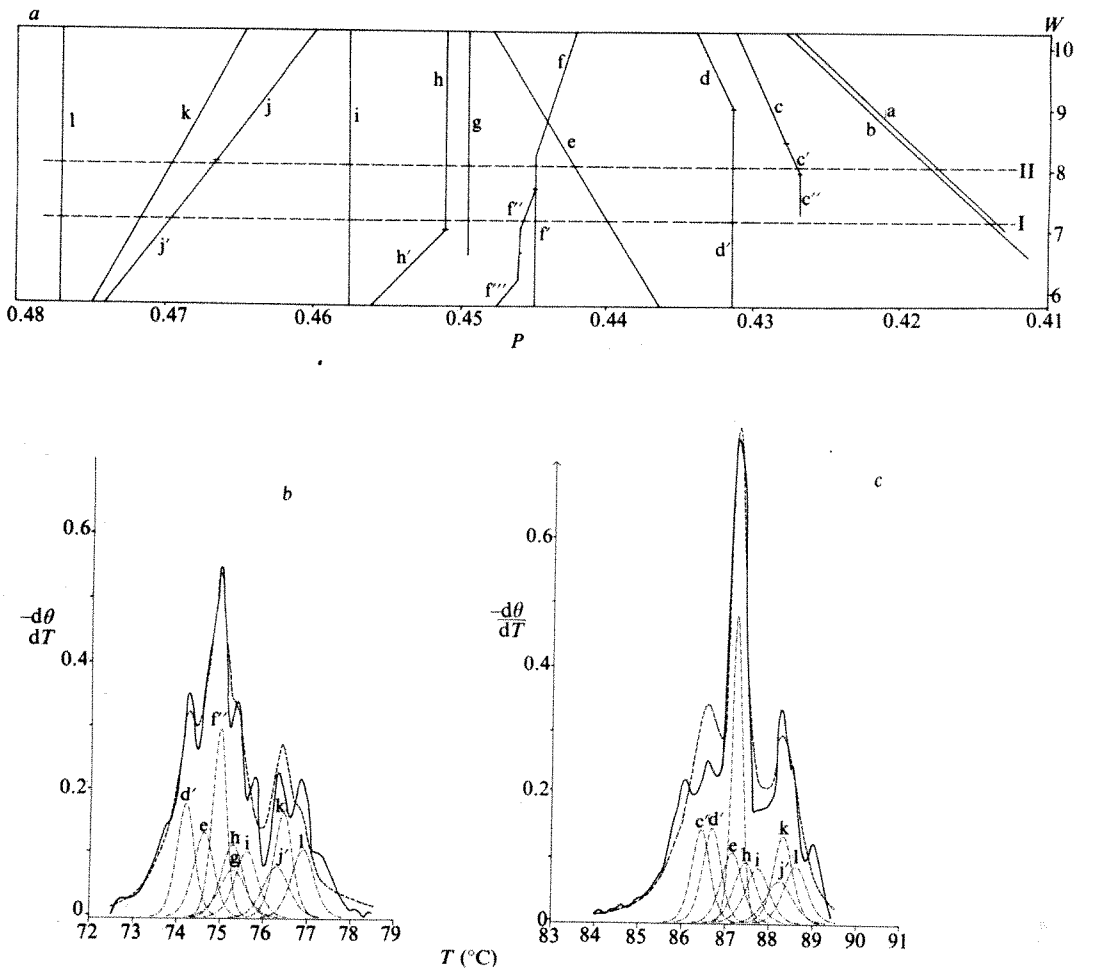

Fig. 2 *a*, Part of the phase diagram of ΦX174 DNA computed from its sequence[21]. Ordinate: $W = V/(f_1 - f_0)$, abscissa: $p = (T - T_{AT})/(T_{GC} - T_{AT})$ (see text and ref. 16). The lines divide domains having different composition of melted and helical segments in the ground state. Neighbouring domains differ by the state of a given stretch of base pairs (only domains differing by the state of at least 200 base pairs are shown). The base pair sequences changing state on crossing the boundaries are: (letters refer to letters drawn in the diagram; numbers indicate base pairs, the origin being the end of gene H (ref. 21)).

b, Solid line: experimental ΦX174 DNA melting profile, 30 mM Na^+ (from ref. 8). Dashed line: computed curve corresponding to intercept I($W = 7.17$) of the phase diagram. Other parameters: $T_{AT} = 55.4$ °C, $T_{GC} = 104.5$ °C, $\beta = 0.084$, $b = 1.114$. This curve differs slightly from that obtained by Azbel[14] because we have used a somewhat different, more accurate sequence[21]. Dashed-dotted curves: melting profiles of individual segments (only the most prominent modes are depicted). *c*, Full line: experimental ΦX174 melting profile, 195 mM Na^+ (from ref. 8). Dashed line: computed curve, corresponding to intercept II ($W = 8.02$) of the phase diagram. Other parameters: $T_{AT} = 68.1$ °C, $T_{GC} = 111.2$ °C, $\beta = 0.081$, $b = 1.114$. Dashed-dotted curves as in *b*.

is the difference in free energy between AT and GC pairs, the abscissa of the phase diagram is given by $p = (T - T_{AT})/(T_{GC} - T_{AT})$ (ref. 16).

As W varies, the size and behaviour of some of the segments remain invariant, such as segment 405–744. Others change, however, such as segment 2,880–3,678 which changes its state at $p = 0.445$ when $W \geq 7.71$, is split into two segments when $W < 7.71$; segment 3,451–3,678 changes state at $p = 0.445$ as above, and 2,880–3,451 changing state at higher p (temperature). Thus size, location, and relative stability of homostable (cooperatively melting) segments inside DNA may be modified by changes in W. These can be induced by various environmental changes. A complete catalogue of the solution parameters acting on W is not yet established, but experimental evidence shows that ionic strength[17,18], *pH* and type of counterion[18] act on the thermodynamic functions entering W and can modify the melting profile of a given DNA.

Extending the phase diagram concept to DNA *in situ*, we may consider changes in W induced by the interaction of DNA with metabolites, activators, histones, polyamines, and so on. These could modify the size, location and relative stability of homostable cooperatively-behaving segments inside the DNA. Such stability switching and shifting could account, at least in part, for the regulatory activity of these agents. Attempts to correlate the complete phase diagram with known genetic features are under way.

We thank Professor W. Fiers for samples of SV40 DNA and Professors P. G. de Gennes and M. Ya'Azbel (who sent us his manuscript before publication) for useful discussions. Environmental factors affecting the quantity of alcohol dehydrogenase in *Drosophila melanogaster*

THE alcohol dehydrogenase gene in *Drosophila melanogaster* has recently been the subject of intense study because it has properties that make it almost ideal for the investigation of genetic fine structure and control in a higher eukaryote[1–3], and for research on the population genetics of enzyme polymorphism[4,5]. There have been reports of genetic variation in alcohol dehydrogenase activity within and between electromorphs[5–10], and of a putative control mutant with half the 'normal' activity[11]. The studies described here show that environmental factors can change the amount of ADH protein in a fly by at least fourfold. They invalidate conventional methods of correcting for body size in studies of the activities and amounts of enzymes in *Drosophila*, and therefore cast doubt on much recent work. They also raise the possibility of an inducible eukaryotic enzyme that is suitable for refined genetic analysis.

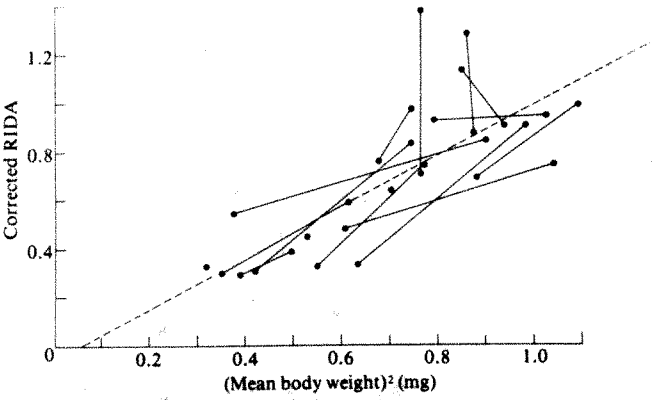

Fig. 1 The regression of corrected radial immunodiffusion area (RIDA) on the square of the mean body weight in batches of 25 4-day old male flies. The dotted line represents the overall regression ($y = 1.045x - 0.051$, $P < 0.001$). Measurements made on the same inbred line in different generations are joined by continuous lines. Inbred lines on which only single measurements were made appear as disconnected spots. The corrected RIDA is the area of the sample divided by the area of a standard extract (a mass homogenate of flies from a *white-honey* stock, used throughout the experiment) measured on the same gel. The flies came from 15 inbred lines, all homozygous for the Adh^S allele, derived from the Edinburgh Kaduna population (established with flies collected in Nigeria in 1949 and maintained since then in population cages). The lines were grown in one-third-of-a-pint milk bottles containing dead-yeast–cornmeal–molasses medium (11 g of yeast per l of vkm) at 25 °C. Adults were isolated as they emerged from pupae. 25 4-day old males were homogenised in phosphate buffer (*p*H 8.0), and the homogenates were passed through a Millipore filter. 4-μl samples of filtrate were introduced into the wells of a 1% agarose gel (*p*H 8.6) containing 2% rabbit antiserum against homogenised *D. melanogaster*. The gels were incubated for 48 h at 25 °C and the precipitin rings stained for ADH with nitroblue tetrazolium–methylene blue[13]. Each point represents the mean of two replicate gels.

The first observation, originally seen in experiments carried out by P. C. Hillier, is that both the activity of the enzyme (measured spectrophotometrically) and its quantity (assayed by single radial immunodiffusion[12]) can rise disproportionately with body weight. This is illustrated in Fig. 1, which shows the relationship between the area of the precipitin ring (strictly proportional, in our gels, to the quantity of enzyme) and body weight in a series of inbred lines homozygous for the Adh^S (slow) allele derived from the Kaduna population[13]. There is a fourfold range in the quantity of enzyme in flies from different cultures. That this is not due solely to genetic variation between the inbred lines is shown by the large differences between generations in one line. Indeed, there is no evidence that the various *SS* lines derived from Kaduna differ genetically in their quantities of ADH. The differences are not due to errors of measurement; the control areas (from the standard extract) are relatively constant from gel to gel, and the average difference between corrected replicate measurements is 11.5%.

The increase in the quantity of ADH with body weight is not linear. In the Kaduna lines it rises proportionally to the square of the body weight (fitting the power curve $y = ax^b$ to the data gives $b = 2.24$). Figure 2 shows that this phenomenon can occur within one inbred line. It gives measurements of single male flies from the Montgomery strain. In this case the amount of ADH is

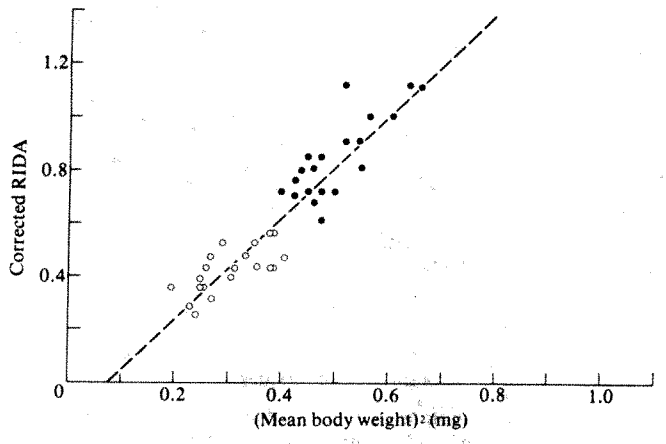

Fig. 2 The regression of corrected RIDA on the square of body weight in single 4-day old male flies from the Montgomery inbred line (homozygous for the Adh^S allele). The dotted line represents the overall regression ($y = 1.915 - 0.144$, $P < 0.001$) which is estimated for comparison with Fig. 1. The measurements were made in two separate generations, represented by open and closed circles. The difference between the generations, due to uncontrolled environmental differences, is very clear. The methods were identical to those given in Fig. 1 legend, except that individual flies were homogenised, and the homogenates centrifuged cold at 13,000*g* for 2 min, and that the gels contained 3% sheep antiserum. Each point represents the mean of two replicate gels.

approximately proportional to the cube of the weight ($b = 3.13$), and once more there is a fourfold range. The significant difference between the slopes of the regressions shown in Figs 1 and 2 suggests that the lines differ in their responses to the environmental factor that increases the quantity of ADH, but this remains to be confirmed.

Because the weight of adult flies is known to be influenced by the conditions of larval growth, we introduced newly hatched first instar Kaduna *SS* larvae into 2.5-cm shell vials containing 10 ml of dead-yeast–cornmeal–molasses medium with various quantities of dead yeast. Four vials had 50 g of yeast per l of medium, four had 10 g, four had 2 g and four had no yeast at all. The quantities of ADH in single 4-day-old adult males that emerged from these vials were measured by radial immunodiffusion. The results, given in Table 1, show that although the progressive addition of yeast increased the mean body weight by about 30%, it more than doubled the average quantity of ADH. Within the treatment groups there was only a slight association between body weight and ADH. It did not depart from linearity, and was significant in only one group (10 g yeast per l). Between the groups, however, the association is very striking, and the differences are highly significant ($P < 0.001$).

Table 1 The effects of different concentrations of dead yeast on the amount of ADH protein

Amount of dead yeast (g per l medium)	No. of vials	No. of 4-day male flies measured	Mean weight mg (s.e.)	Mean RIDA mm^2 (s.e.)
0	4	18	0.719(0.015)	30.13(1.37)*
2	4	17	0.791(0.021)	47.88(2.89)*
10	4	18	0.901(0.015)	81.83(2.02)
50	4	20	0.906(0.018)	80.70(1.73)

1st instar larvae were obtained from eggs deposited by Kaduma Adh^S homozygotes on laying dishes, and were grown in 2.5-cm shell vials containing 10 ml of medium (50 larvae per vial) at 25 °C. The methods were otherwise identical to those given in Fig. 2 legend. The asterisks represent means based on RIDAs that were significantly heterogeneous between vials ($P < 0.05$). Despite this heterogeneity the differences in RIDA between treatments are highly significant ($P < 0.001$).

These findings have several implications. The amount of enzyme is 'allometric' with body weight, rather than strictly proportional to it. This means that conventional ways of correcting for body size (dividing the activity or quantity of enzyme either by the body weight itself or by the total soluble protein, which is proportional to body weight) may give seriously misleading results. Supposed genetic differences in the activity or quantity of enzyme may merely reflect persistent disparities of body weight and/or the conditions of culture. This uncertainty applies to the report of a twofold difference in the quantity of ADH between genotypes[7], and to the recent claim that a 30% difference between a line selected for resistance to ethanol and an unselected control was due to the action of 'regulatory' genes[14]. It may also apply to work on other *Drosophila* enzymes, for which the effects of variations in the medium have not been studied. Our results suggest that screening for activity mutants may be greatly improved by a careful control of the medium. We note that disparities between lines in the conditions of culture may seem to be genetic because microorganisms can be passed on from the medium of the parents to that of their offspring.

The causes of the changes in the quantity of ADH are unknown. They could be due to an increased synthesis of enzyme in favourable conditions, to a decreased breakdown, or to changes in the time course of synthesis or breakdown. These possibilities are being studied, but in any event there is evidence that the precipitating factor is some part of the larval environment correlated with the quantity of yeast. A constituent or product of the yeast is the most obvious candidate. Because the flies were raised on dead yeast the factor is unlikely to be ethanol. Two per cent ethanol added to medium containing 2 g yeast per l does not increase the quantity of ADH (unpublished observation). If the changes prove to be a case of induction, and if the inducing substance can be identified, these observations will offer interesting possibilities for the study of eukaryotic gene control.

Endorphins in Mental Health Research

Edited by Earl Usdin, William E. Bunney Jr. and Nathan S. Kline
This collection of papers provides an invaluable account of the current state of research in this new field of neuroscience. The vital issues covered are bound to stimulate a renewed controversy and further research activity – both from those already directly involved and from those who feel that they cannot ignore the increasing relevance of endorphins to their own work.

The Mathematics of Finite Elements and Applications III, MAFELAP 1978

edited by J. R. Whiteman

July/August 1979, c 520pp., £15.00/$31.50 0.12.747253.3

This volume records the Proceedings of the Third Conference on the Mathematics of Finite Elements and Applications, which was held at Brunel University in 1978. The decision to hold the conference followed the success of the previous two. The book contains the 10 main invited papers and 30 contributed papers, which were presented as lectures at the meeting, together with the abstracts of some 30 other papers that were presented in poster sessions. As before, the aim of the conference was to bridge the gap between the mathematical theory of finite elements and their applications. In particular, the main invited lecturers and the contributed papers were chosen so as to give coverage to as many as possible of the developments that have taken place in the finite element field in the three years since the last conference. Several chapters contain suggestions by the authors as to possible future paths that finite element techniques may take.

Frontiers of Speech Communication Research

edited by B. Lindblom and S. Öhman

August 1979, xxvi + 394pp., £18.80/$39.50 0.12.449850.7

The variety of new theories and related research is mirrored by the range of topics covered in this book: the quantitive modelling of the human vocal tract and its acoustical properties; acoustic phonetic description of various languages; the perception of speech and the development of objective measures of speech quality; applications of speech research; and the development of distinctive feature frameworks for linguistic theory. These original research reports, together with a number of review articles, provide a broad, up-to-date survey that makes the book a valuable reference work. The scope of the contributions will attract students and professionals engaged in research into speech communication, and those involved in the related fields of speech pathology, psychology, physiology and acoustics, and relevant areas of computer science and engineering.

Cognition and Perception Series

Decision Processes in Visual Perception

D. Vickers

August/September 1979, viii + 406pp., £21.60/$45.50 0.12.721550.6

The principal aim of this book is to present a theory of some of the fundamental mechanisms involved in the quantitative processing of visual information by human beings. In developing the theory, the book provides a detailed, constructive review of the various experiments and alternative hypotheses in each field of research. Throughout, the author relates his theory to other approaches, and presents it as the outcome of a logical sequence of alternative hypotheses. The various theoretical notions are dealt with in a concrete, intuitive way rather than a purely mathematical one, but abundant references are given to enable the reader to evaluate the argument in a more rigorous manner. The book will have a wide appeal to advanced undergraduates and researchers in experimental and cognitive psychology, particularly in the areas of perception, psychophysics and human information processing.

Drug Carriers in Biology and Medicine

edited by G. Gregoriadis

August/September 1979, c 300pp., £21.80/$46.00 0.12.301050.0

In theory, target selectivity for drugs can be achieved either on the basis of differential sensitivity or differential accessibility. However, it has only been in the last few years that the latter method has been considered practicable, by taking advantage of structures on the cell surface to bring about selective concentration of drugs by means of appropriate carriers. This is the first book to bring together work on a variety of drug carriers, and its publication now is evidence of the large amount of work already done and the success that has been achieved. The contributors survey the various approaches to the problem that have attempted using different types of carrier, and speculate on the possibilities of future research. The carriers dealt with include macromolecules and cells with homing properties harvested from biological systems, and synthetic carriers such as liposomes tailored to fulfil particular needs.

Electronic Imaging

edited by T. P. McLean and P. Schagen

August 1979, xviii + 522pp., £29.00/$61.00 0.12.485050.2

This book consists of the papers presented at an International Symposium sponsored and organised by the Rank Prize Funds, and held at the Royal Society, in September 1979. The aim of this symposium was to bring together experts on all aspects of electronic imaging, to exchange ideas and to benefit from their differing approaches to problems in this field. All the papers were given by invitation, which provided the opportunity for a balanced coverage of the many aspects of the subject: the pick-up display and recording of images of visible scenes, the processing of such images by electronic means, the sensing and use of images originating from non-visible radiation, such as infrared, microwave or ultrasonic and the interpretation by the eye-brain complex of the images presented to it.

British Coastal Shrimps and Prawns

Keys and Notes for the Identification of the Species

G. Smaldon

July 1979, vi + 126pp., £4.50/$9.50 0.12.659260.6

British Coastal Shrimps and Prawns is a delightfully illustrated synopsis, which should be of wide interest. Searching for these well-known animals is a popular summer occupation for many and a livelihood for a few, as the larger ones are of culinary importance. There are over 40 different species to be found around British shores. With this synopsis it will now be possible to identify them accurately, thanks to the general accounts of the biology of each species aided by the illustrations, which carefully portray characters of systematic importance without taking away any of the fascination of these lively crustaceans.

Like previous synopsis, this one is designed to be a working field and laboratory guide for professional and amateur biologists. It bridges the gap between popular field-guides and rare taxonomic treatises and monographs. This book will be of considerable value to fish and wild life biologists, natural historians, conservationists, oceanographers and marine scientists.

Cobalt in Biology and Biochemistry

R. S. Young

August/September 1979, x + 148pp., £11.80/$25.00 0.12.772750.7

Cobalt is in a unique position amongst the rarer heavy metals found in biological systems. It plays an essential role in ruminant nutrition, functions as a key element in Vitamin B_{12} and there is extensive evidence on the beneficial effects of small quantities of this metal on growth and development in many plants, animals and micro-organisms. With over forty years of experience of all aspects of cobalt, Dr. Young is eminently placed to make a critical assessment of such published investigations. This book takes the form of a review of the literature of cobalt and a reference manual that will enable researchers to benefit from an insight into the techniques employed and data obtained by others working in different areas of science. The cobalt content of fertilizers, waters and plants, cobalt in human and animal nutrition and the effects of cobalt on enzymes and micro-organisms are the subjects of just some of the chapters. The text is well documented with over a thousand references, allowing the agricultural, medical, biological and chemical researcher or student ample scope to pursue his own particular interest and to aquire ideas from other areas of science which may be applicable to his own.

The Design and Analysis of Longitudinal Studies

Their Role in the Measurement of Change

Harvey Goldstein

August/September 1979, xvi + 200pp., £11.80/$25.00 0.12.289580.0

The principal aim of this book is to set out the theoretical and practical problems of longitudinal studies within the general framework of studies concerned with understanding the process of change, in particular with developmental studies of children. The seven chapters are designed to lead the reader through the various stages of study design and analysis. They bring together in a systematic manner a widely scattered literature and assemble it in a coherent form. The topics dealt with include the practical problems of planning a study, the problems of sampling, the choice of suitable instruments to measure change, the development of statistical models for analysing change, the setting up of norms or standards over time and the design of computer programmes for processing longitudinal data. This will make stimulating and enlightening reading for students and research workers concerned with longitudinal studies of human populations as well as experimental studies, for example, of animals and plants involving longitudinal data.

Applied Problems in Memory

edited by M. M. Gruneberg and P. E. Morris

August/September 1979, xiv + 290pp., £12.40/$26.50 0.12.305150.9

Memory plays a vital part in all human activities and a proper understanding of how it works in real life is of great importance to many practical and social problems. However, for many years there has been less emphasis on research into applied problems of memory than into theoretical aspects. The present book examines applications of memory research with contributions from eminent workers in a number of areas. The book covers an impressive range of problems in which psychologists have recently been engaged, from the more obvious improvements in techniques for better remembering and in education, to less evident areas such as reading, memory in the aged, effects of stress, memory for skills and disorders of memory. The wealth of practical examples given throughout the text contribute to make a highly readable account of the subject. Within its wide scope, the book has a great deal to offer, not only to cognitive psychologists and workers in educational, clinical and industrial psychology, and in ergonomics, but also to anyone concerned with practical problems of memory at all levels.

Bacteria and Mineral Cycling

T. M. Fenchel and T. H. Blackburn

August/September 1979, xii + 266pp., £14.60/$31.00 0.12.252750.X

This book describes the influences of bacterial metabolism on the chemical environment of the biosphere. Its readers will include general microbiologists who want to find out about the ecological significance of micro-organisms; ecologists whose microbiological background is limited yet who wish to understand the role of bacteria in natural ecosystems; postgraducates in microbial ecology; and, finally, applied scientists — such as soil scientists or environmental engineers — involved with microbial ecosystems. The discussion of the energetics of bacterial processes serves as a general structure for most of the topics in the book since such considerations may afford insight into which processes are important in natural ecosystems. Within this basic framework, two major aspects of bacterial metabolism are stressed. Firstly, the chemical evolution of the biosphere and secondly, the manner in which different element cycles interconnect in natural ecosystems. Appendices are included with information that will enable those with only elementary knowledge of microbiology, energetics and ecology to understand the

Announcing Two New Journals from Academic Press

CRETACEOUS RESEARCH

Editor: R. A. Rayment, Paleontologiska Institutionen, Uppsala, Sweden

Editorial Board:

Peter Bengston (Sweden). Pierre-Yves Berthou (France). Tove Birkeland (Denmark). John Michael Hancock (UK). Erle G. Kauffman (USA). William James Kennedy (UK). Tatsuro Matsumoto (Japan). Dmitrij Pavlovich Naidin (USSR). Viera Scheibnerova (Australia). Seymour O. Schlanger (USA). Jorn Thiede (Norway). Hans R. Thierstein (USA).

Publication: Quarterly
Volume 1, Number 1 scheduled for March 1980

Subscription: Volume 1, 1980 £30.00 (UK only)
Overseas price to be announced

The Cretaceous system is of interest in many different disciplines, including palaeontology, stratigraphy, geophysics, oceanography, petroleum geology, geochemistry, sedimentology and tectonics. This new and wide-ranging journal aims to cover all these fields in their applications to Cretaceous research. It will also consider methodological papers if they can be applied to problems of interest to workers on Cretaceous rocks, and will give an important place to regional geology. Articles both long and short will be accepted but priority of publication will be given to short reports of research papers, in order to reduce publication delays to a minimum. All papers will be refereed, and may be submitted in English or French — papers in French must have a detailed summary in English. There will be scope for book reviews and the proceedings of symposia on subjects of relevance to the Journal's readers. *Cretaceous Research* will aim at high-quality contributions from the outset, and will be of great interest and value to all petroleum companies, libraries and individual workers on the Cretaceous or in foraminifera, plate tectonics, deep-sea research, regional geology or stratigraphy.

APPETITE

The Journal for Research on Intake, its Control and its Consequences

Chief Editors:

David Booth
Department of Psychology, University of Birmingham, P.O. Box 363, Birmingham B15 2TT, England.

Gordon J. Mogenson
Department of Physiology, Health Sciences Center, University of Western Ontario, London, Canada, N6A 5C1.

Judith Rodin
Department of Psychology, Yale University, Box 11A Yale Station, New Haven, CT 06510, USA.

Editorial Board 1979-1980:

G. A. Bray (USA). A. N. Epstein (USA). S. Garattini (Italy). A. E Harper (USA). D. J. McFarland (UK). P. R. McHugh (USA). E. Montgomery (USA). S. Nicolaïdis (France). D. Novin (USA). R. M. Pangborn (USA). E. T. Rolls (UK). P. Rozin (USA). F. J. Simoons (USA). U. Ungerstedt (Sweden). G. T. Wilson (USA).

An Advisory Board is to be announced.

Publication: Quarterly
Volume 1, Number 1 scheduled for March 1980

Subscription: Volume 1, 1980 £27.50 (UK only)
Overseas price to be announced

This new interdisciplinary journal concerns appetite — the tendency to seek and consume substances, be they food, water or any other ingestable materials — in all its aspects. It will cover the basic appetitive and ingestatory mechanisms of interest, including neural, systematic physiological, biochemical, pharmacological, sensory, psychological, social, cultural and economic processes. The applied study of appetite may be *clinical* (weight control, obesity, dietary health risks, anorexia nervosa and malnutrition), *industrial* (sensory evaluation, consumer research on foods and drinks and feed regulation for animal production) or *zoological* (conservation and pest control). Papers are invited from any of these areas, although material submitted should have substantial relevance to intake or attitudes to ingestable substances. An important aim of the journal will be to publish innovatory papers crossing the traditional boundaries between disciplines: reviews, comments and mini reviews with an integrative bias are welcomed as well as reports of new investigations. There will be a place for book reviews, abstracts or reports, summaries of papers published elsewhere, bibliographies and announcements of relevant meetings — indeed anything appropriate to the general area of appetite. This major new publication, while not affiliated to any society, is intended for researchers in a wide range of disciplines including psychology, anthropology, zoology, pharmacology, psychiatry, medical research, nutrition, food science and applied social science.

Selection in the social insects

Brian Charlesworth

Caste and Ecology in the Social Insects. By G. F. Oster and E. O. Wilson. Pp. 352. (Princeton University Press: Princeton, New Jersey, and Guildford, UK, 1979.) Hardback £12.50; paperback £4.70.

In the *Origin of Species*, Darwin wrote: ". . . I believe that natural selection, by acting on the fertile ants . . . could form a species which should regularly produce neuters, all of large size with one form of jaw, or all of small size with widely different jaws; or lastly, and this is the greatest difficulty, one set of workers of one size and structure, and simultaneously another set of workers of a different size and structure". He attributed this to "family selection": "slight modifications of structure or of instinct, correlated with the sterile condition of certain members of the community, have proved advantageous: consequently the fertile males and females have flourished, and transmitted to their fertile offspring a tendency to produce sterile members with the same modifications". Apart from the brief formulations of kin selection by Fisher and Haldane in the 1930s, relatively little was added to this wonderful insight of Darwin's about the evolution of the social insects until W. D. Hamilton's seminal papers in the early 1960s. Since then, interest in this fascinating subject has steadily grown.

Oster and Wilson's book is a synthesis of recent work, with particular emphasis on the problem of the selective factors affecting the numbers and kinds of sterile castes. Professor Oster is well-known for his outstanding contributions to mathematical ecology, and Professor Wilson for his leadership in the field of sociobiology. One would therefore expect this book to be a formidable combination of theoretical skills and wide knowledge of the natural history of the social insects. This expectation is certainly fulfilled. The book alternates between theoretical analyses and discussions of the relevant biological facts. Although the mathematical derivations are relegated to appendices, I suspect that many biologists will, like myself, find the theory rather heavy going. Nonetheless, many important questions are discussed, and workers on the evolution of social behaviour will need to study this book with care.

Chapter 1 provides an introduction to the problem of explaining the varied behavioural repertoires of the workers, and (in some groups) the existence of distinct physical castes. The authors state their intention of attacking the problem mainly through the concept that "castes and division of labour are subject to optimisation by natural selection at the colony level". (By colony-level selection, they mean Darwin's family selection; curiously enough, Darwin's contribution is never mentioned.)

Chapter 2 reviews the extensive data on different types of colony life-cycles. Some interesting suggestions are put forward concerning the selective factors which may influence the ways in which colonies can be founded (swarming as opposed to foundation by reproductives only, single as opposed to multiple queens, and so on), and there is a detailed theoretical analysis of the optimal allocation of resources between workers and reproductives during the development of a colony. This seems to provide a convincing explanation for the fact that, in temperate-zone species, reproductives are usually produced as a burst towards the end of the season, with the production of workers being simultaneously terminated. To my mind, this is the most successful application of the theory to a real-life problem in the whole book, as the theoretical predictions are not intuitively obvious, but follow from a plausible model. A note of caution is in order, however, as recent theoretical work suggests that the frequency of workers within a colony may be subject to control by kin selection or parental manipulation. A colony-level selection approach to this problem may not, therefore, be entirely satisfactory.

Chapter 3 is a discussion of the genetic basis of selection on social insects, particularly in relation to the sex-ratio problems originally treated by Trivers and Hare. I found this chapter somewhat disappointing. It assumes that selection should act to maximise either the fitness of the colony, the inclusive fitness of workers, or the inclusive fitness of the queen. It is not at all clear what the relevance of the colony's fitness is to a question such as the optimal allocation of resources between male and female reproductives, as evolutionary change in this variable must proceed by the substitution of genes which express themselves in individuals (queens or workers). Furthermore, considerable algebraic contortions have to be gone through in order to define the fitness parameters correctly, and to obtain solutions to the maximisation problems. A simpler approach would have been to use the standard population genetics methods for determining the values of the population strategies which are immune to invasion by rare genes causing deviant strategies — Maynard Smith's concept of the Evolutionarily Stable Strategy (ESS). These methods have been successfully applied to the sex-ratio problem by E. L. Charnov and others, and have the advantages both of simplicity and of being based firmly on gene frequency analysis. Chapter 3 also contains a rather misleading account of the ESS concept, which conveys the impression that an ESS is equivalent to a Nash equilibrium in standard games theory. But in the animal conflict models originally studied by Maynard Smith, members of a population playing a strategy S_1 have the fitness associated with contests between pairs of S_1 individuals. A rare mutant playing a different strategy S_2 will, to a good approximation, have the fitness associated with contests between S_2 and S_1. S_1 is an ESS if the former fitness exceeds the latter for all values of S_2. This has nothing in common with a Nash equilibrium, which involves a pair of opponents with different interests. Nash equilibria may be relevant to situations where different members of the population have conflicting interests (for example, the queen-worker conflict studied by Oster and Wilson), but the ESS concept is broader.

Chapter 4 gives a lucid account of the major facts about temporal and physical castes. Chapter 5 outlines the concepts underpinning the theoretical models of caste evolution developed in later chapters, the central idea being that of the "caste distribution function" or CDF, which specifies the distribution of the numbers of workers with respect to physical and behavioural caste, as a function of time, throughout the colony's development. The CDF is assumed to be adjusted by colony-level selection such that the total number of reproductives is maximised. Chapter 6 develops ths model, using dynamic optimisation theory to solve for the optimal CDF. As the authors make clear, the problem is not so much why there should be distinct castes, but why there are usually so few. They claim that, in

general, a size distribution of workers which precisely matches the distribution of size of available resource items is not to be expected. Their argument relies heavily on the concept of "fidelity cost", which assumes that an abrupt increase in the number of individuals in a given class creates an energy cost to the colony. This is an interesting idea, but seems rather difficult to evaluate empirically, in view of the necessarily arbitrary way in which the fidelity cost is introduced into the models. Chapter 7 is concerned with foraging strategies of workers. Chapter 8 is a useful discussion of the role of optimisation theory in evolutionary biology, and Chapter 9 is a brief survey of unsolved problems. As the authors make clear, both here and in the preface, the major factors determining the evolution of the detailed features of caste ratios and behavioural flexibility remain largely unknown. Nevertheless, their use of quantitative models highlights the problems very clearly and should prove very stimulating to research in this area. □

Brian Charlesworth is Lecturer in Biology at the University of Sussex, Brighton, UK.

Affinity chromatography

An Introduction to Affinity Chromatography. By C.R. Lowe. Pp. 253. (North-Holland: Amsterdam, New York and Oxford, 1979.) $29.25; Dfl60.

THIS volume is part of a series on laboratory techniques. The first four chapters consist of an introduction to chromatography, and accounts of basic concepts, chemistry and techniques of affinity separations. Chapter 5 is a selection of applications (protein-enzyme area), and a separate chapter covers regulatory macromolecules and more complex structures (although how antibody-antigen systems fit this category escapes me). The last two chapters are concerned with analytical applications and special techniques (very useful). The book covers most of the earlier work in the field: 9 references out of the 240 are 1977 or later.

The author has many thoughtful remarks to make for users of affinity chromatography. Rather than present a flawless up-to-the-minute review, Dr Lowe provides a valuable set of guidelines which should inspire rather than weary the reader. Because the technique is developing so rapidly some parts of the book are incomplete. Thus, it is now clear that triazine dyes are widely used as affinity ligands, their main advantage being the combination of capacity and selectivity. A slightly misleading comment on p455 suggests that all albumins will bind to Cibacron Blue columns when this property refers to human albumin only.

In the next edition, I would like to see some of the following recent advances discussed: the receptor purification advocated by Baulieu, involving alteration of the molecular weight of a protein using soluble dextran-ligand conjugates, electrophoretic desorption of high affinity biospecific adsorbents, light-reversible affinity ligands, and high performance affinity chromatography.

The sections on ligand concentration, temperature effects, the importance of ligand preassembly and the concept of group specific affinity matrices did not do justice to the author's work in these areas. I would also have liked to see a warning of the toxicity of *s*-trichlorotriazine (cyanuric chloride).

Pride of place in accounts of affinity chromatography goes to the now famous use of immobilised oxamate to adsorb lactate dehydrogenase in the presence of NAD(H). Dr Lowe's book leaves this bastion of theoretical preconception unassaulted, although Wood *et al.* have convincingly shown (1977) that replacing CNBr with triazine chemistry abolishes the biospecificity of the oxamate column.

Apart from the above minor criticisms, I found the balance between commercials, laboratory methods (for which Dr Lowe has an obvious flair) and theory enjoyable and well thought out. **P.D.G. Dean**

P.D.G. Dean is Senior Lecturer in the Department of Biochemistry at the University of Liverpool, UK.

Biological semiconduction

Dielectric and Electronic Properties of Biological Materials. By R. Pethig. Pp.376. (Wiley: Chichester, UK, and New York, 1979.) £15.

THE possibility that electronic energy bands exist in certain solid-state biological systems, playing a role in energy migration (Möglich and Schön; Jordan 1938) and electron transfer (Szent-Györgyi, 1941) has been around for over 40 years. During this time there has occurred a small but steady amount of theoretical and experimental progress on biological semiconduction, that is, on the electron transfer problem. Earlier work tended to show the conductivities were too low for biological significance, but with passage of time, the effects of hydration, and of charge-transfer, in inducing appreciable electronic conduction in proteins, all go towards increasing the prospects of a role of semiconduction in certain biological processes. The recent demonstration of high conductivity in reduced cytochrome c_3 by Inokuchi and coworkers, is another step in the same direction. Dr Pethig's book is aimed at introducing newcomers from a variety of disciplines to the field, and these are to be welcomed, as the need to increase the ratio of facts to speculations is rather urgent.

Very sensibly Pethig's first three chapters deal successively with dielectric theory, the intrinsic dielectric properties of biopolymers, and the effects of solvation on the dielectric properties. In these he established the basic solution properties, and then goes on in his fourth chapter to the effects of water on the solid-state behaviour, dealing with X-ray studies and water adsorption. In his fifth chapter Pethig outlines interfacial dielectric phenomena, the Maxwell-Wagner effect and its developments. Although this treatment is clear, I believe it could usefully have been a greater length, as the separation of Maxwell-Wagner from dipolar and hopping loss mechanisms is a fundamental problem in this field. Per contra, the sixth chapter dealing with dielectrophoretic studies is mainly of interest in connection with preparative separation methods, and is slightly off the main theme of the book. Chapter 7 deals with biological membranes and tissues, with brief notes on black lipid membranes, and includes three pages on the sometimes controversial effects of electromagnetic fields. With the final two chapters, 8 and 9, we come to the main part of the book, in which the author's own research interests are to be found. Chapter 8, on electrons, energy levels and energy bands, provides the basic background for crystalline and amorphous semiconductors, and includes an account of band gap and band width calculations for biopolymers, from the pioneer work of M.G. Evans and J. Gergely (1949) to the present. Chapter 9 sets out the experimental data on semiconductivity, Hall effects, charge-transfer interactions, piezoelectric effects and so on for proteins, DNA and other biological molecules. Photoconductivity is mentioned, but rather too briefly in view of its possible importance in vision and photosynthesis. Chapters 8 and 9, however, could scarcely be comprehensive in the space available, and Pethig's approach has been to take a few selected topics in depth. So, for example, there is a thoughtful appraisal of the effects of adsorbed water on conductivity, and an account of Pethig's own work on the methylglyoxal-protein system, in connection with Szent-Györgyi's recent suggestions concerning carcinogensis.

I believe this book gives an attractive introduction to its field. Mathematics are kept within the bounds necessary for a general readership, and in spite of the author's engineering background the emphasis is always on molecules rather than equivalent circuits. It is logically arranged, reads easily, and there is an ample supply of references. As a personal preference, I think a chapter summarising

the well-established field of ionic conduction in membranes, might have added to the value of the book, and formed a bridge to already well-established areas of electrophysiology. Where ionic and electronic conductivity exist side by side, there is a real problem in distinguishing one from the other. But Dr Pethig was probably wise not to trespass beyond his brief of electronic properties, since this is a neglected area of biophysics at present, and I believe this book makes a valuable contribution towards remedying this neglect.

D.D. Eley

D.D.Eley is Professor of Physical Chemistry at the University of Nottingham, UK.

Photochemistry of small molecules

Photochemistry of Small Molecules. By Hideo Okabe. Pp. 431. (Wiley: Chichester, UK, 1978.) £24.55.

ADVANCES in techniques, made over the past decade or so, have greatly facilitated detection of photochemical primary products and made possible detailed studies of photodissociation dynamics. The information obtained, coupled with much new experimental data on the reactivities of ground state and excited atoms and radicals, has provided the basis for an improved understanding of photochemical processes. Dr Okabe's book has been written to cover the progress made in the gas phase photochemistry of molecules containing up to five atoms.

The contents of the book fall essentially into three parts. Two chapters deal with the principles of spectroscopy and of the primary photochemical process; the introductory section is concluded with a chapter on experimental techniques. The author has chosen here to emphasise certain topics that are of interest to himself; and they are topics of importance often ignored elsewhere. The thermal contribution to photodissociation, atomic resonance absorption and emission, and deviations from the Beer-Lambert Law are dealt with in detail, as are energy and angular distributions in photofragments, and the determination of dissociation energies. The chapter on techniques is similarly concerned with certain special aspects rather than with a comprehensive overview. The order of presentation is sometimes unexpected, with detail preceding generalisations. For example, a mathematical treatment of band intensities is given in a section before, and unrelated to, that in which observations of intensity distributions are reported and the Franck-Condon principle stated.

The central section of the book consists of four chapters dealing with the quenching and reactions of excited atoms, and the photochemistry of diatomic to pentatomic molecules. For some 80 molecules, the spectroscopy and photochemistry are discussed in the light of information available up to July 1977. Although the huge amount of factual material presented necessarily precludes a deeply critical approach, the review is structured and readable.

A final chapter of the book is devoted to some topics related to photochemistry: isotopic enrichment, photochemical air pollution of the troposphere and stratosphere, and the photochemistry of the atmospheres of Mars, Venus and Jupiter. No more than an introduction can be given to these subjects in a total of 35 pages, but the chapter will provide a stimulus to the reader, as well as guiding him to more detailed references.

The author states that his book is aimed at the physical chemist, spectroscopist and atmospheric scientist interested in photochemistry. The level and content seem about right for this readership. A non-specialist would probably find the first chapters inadequate, and the review part too detailed, for the book to provide an introduction to photochemistry. But, for the practising photochemist, Dr Okabe has provided a most valuable reference book.

R. P. Wayne

R. P. Wayne is Lecturer in Physical Chemistry at the University of Oxford, and Dr Lee's Reader in Chemistry at Christ Church, Oxford, UK.

Asbestos sourcebook

Asbestos. Vol.1: *Properties, Applications and Hazards.* Edited by L. Michaels and S. S. Chissick. Pp. 553. (Wiley: Chichester, UK, and New York, 1979.) £25.

IN 1976, Dr Michaels and Dr Chissick, of the University of London, could discover no comprehensive source book on all aspects of asbestos. This first of two volumes is the result of a useful, and at times entertaining, attempt to provide such a book. The volume covers the mineralogy, chemistry and physics of asbestos, its use, monitoring, identification, and substitute materials; and five chapters are devoted to asbestos-related diseases. There are also contributions on attitudes to asbestos, and dealing with asbestos problems.

Each chapter was commissioned with an obviously careful brief to be comprehensive, not too technical and independent of other chapters. This has led to some repetition, for example, of the different varieties of asbestos and of the history of asbestos-related diseases. But this does not detract from any individual chapter and is only a slight annoyance to reviewers or other cover-to-cover readers.

Clearly, the brief that the editors gave themselves was to seek moderation. The contributors were carefully selected to exclude members of the asbestos industry and its declared opponents. This has worked remarkably well, as the contributions are well balanced without the extreme views often expressed on the emotive subject of the hazards of asbestos. This balance has been maintained effectively except in the chapter on attitudes to asbestos. There, the moderate discussion of attitudes of governments, industry and unions becomes more extreme itself when considering the extreme viewpoints of pressure groups and in the media. It was a pleasure to see the publication of such a positive response.

It was also a pleasure to see aired (for example, on page 385) certain of the inter-professional disputes which have been well-known among research workers, but have rarely been made public. This is a good move towards more openness in science.

In a series of commissioned chapters, not all can be of uniform standard. The introduction contains definitions (misleadingly headed Bibliography) of some terms. The first is of asbestos bodies, but the definition is of a fibre; the second contains one of those misprints prized by collectors — asbestosis is characterised by diffuse *intestinal* fibrosis — although it is argued on page 421 that the fibrosis is not "interstitial"; the radiographic classification given was issued by the International Labour Office in 1958, but the first version specifically to cover the radiographic changes related to asbestos exposure was not issued until 1971. The chapter on the clinical features of asbestos-related disease seems to treat the subject most superficially, particularly by comparison with the adjacent chapters. There were also a few other odd statements such as road death statistics are a hazard to health (page 330), and asbestos is the only known naturally occurring fibrous mineral (page 306). More seriously, there was no specific mention of the Medical Research Council as a source of information despite the many years of research on asbestos undertaken by its staff.

However, the overall impression is of a most comprehensive source book, useful to almost everybody who needs to discover information about asbestos. It goes a long way towards the editors' aims of public education. The only missing information seems to be the contents list for volume two.

Charles E. Rossiter

Charles E. Rossiter is Head of the Division of Computing and Statistics at the Clinical Research Centre, Harrow, UK.

Desert ecosystems

Arid-Land Ecosystems: Structure, Functioning and Management. Volume 1. Edited by D.W. Goodall, R.A. Perry and K.M.W. Howes. Pp. 881. (Cambridge University Press: Cambridge, 1979.) £45.

THIS volume is one of two that will give an overall account of arid-land studies, one of the themes of the International Biological Programme. Although much of the official IBP work was carried out in the USA, a considerable amount of similar work was also carried out in other countries at the same time, and much of this information has also been included. Unfortunately, and in spite of efforts by the editors, it has not proved possible to provide global coverage of arid regions. There is no account of South American deserts and the Sudan, a country with one of the largest desert areas, is only mentioned in passing. However, the areas that are described include North America, northern Africa, southern Africa, Australia, and South-West and Central Asia. The climate, soils, geomorphology, hydrology, flora and fauna are covered and the processes that operate within, and control, the ecosystem are dealt with under component, atmospheric, soil, plant and animal processes.

The editors' task must have been a nightmare for in spite of international cooperation investigators still seem to have operated within their own sub-set of published work and conventions, often set by linguistic or old colonial spheres of influence. This can give rise to reliance on a very distorted range of literature or undue emphasis on a personal field of interest in a review article. Thus, one regional account emphasises productivity, another phytosociology, and in some accounts animals receive scant attention. The characterisation of regional climate is similarly diversely treated. In one account simplified 'Walter Klimadiagramm' are given, another resorts to rainfall tables, a third makes use of maps with isohyets, and others give the 'Walter Klimadiagramm' in full. Standardisation of representation would have allowed comparison and integration to be made more easily.

The part of the volume devoted to processes is more satisfactory and includes an excellent chapter on diversity and niche structure in desert communities by E.R. Pianka. Chapters on radiation, precipitation and soil processes deal well with specifically desert conditions. Other chapters treat topics more generally.

This book has not managed to distil the knowledge accumulated in the IBP studies on arid ecosystem structure and function in a unified way. It would be unfair, however, to be too critical as it is difficult to give constructive suggestions on how a more satisfactory account could have been achieved. It is perhaps best to accept the volume for what it is — a mammoth compendium of information on many of the world's desert ecosystems.

M. J. Chadwick

M. J. Chadwick is Senior Lecturer in Ecology at the University of York, UK.

Prosimian behaviour

The Study of Prosimian Behavior. Edited by G.A. Doyle and R.D. Martin. Pp. 696. (Academic: New York, San Francisco and London, 1979.) $49.50.

The Study of Prosimian Behaviour is that rare pleasure: a book which fully achieves what it sets out to do. Its articles survey current knowledge of the prosimians, tabulate that knowledge by species and subject, and point out important hypotheses or conclusions for future study. From the opening chapter, in which Petter and Petter-Rousseaux give a revised classification, as well as the first full set of species distribution maps since Hill's tome *Primates: Comparative Anatomy and Taxamony,* Vol.1 (Edinburgh University Press, 1953), it is clear that this is now the standard reference for most aspects of prosimian behaviour. As such, it belongs in any university library.

The editors are to be congratulated on assembling articles of fairly standard format, with a minimum of repetition, although gestation lengths are given in three of the chapters and Martin and Charles-Dominque's basic decoding of home range and social structure in nocturnal forms enters at least three others. One might quibble that social structure of the diurnal species is under-represented, but this has been dealt with in recent books by A.F. Richard *(Behavioural Variation: Case Study of a Malagasy Lemur;* Bucknell University Press, Lewisburg; Associated University Presses, London, 1978 and edited by I. Tattersall and R.W. Sussman (*Lemur Biology*; Plenum, New York, 1975).

Chapters cover classification (J-J. Petter and A. Petter-Rouksseaux), phylogenetic and allometric aspects of behaviour (R.D. Martin), reproduction (R.N. Van Horn and G.G. Eaton), maternal behaviour (P.H. Klopfer and K.J. Boskoff), development (G.A. Doyle), learning (B.J. Wilkerson and D.M. Rumbaugh), vocal communication (J-J. Petter and C.M. Hladik), diet (C.M. Hladik), spatial distribution (J.I. Pollock), vision (G. Pariente), olfaction (A. Schilling), locomotion (A. Walker), field studies of lorisids (P. Charles-Dominque and S.K. Bearder), and a study of *Tarsius bancanus* (C. Niemitz).

One theme which runs through the book is the importance of nocturnal life, where the prosimians may give us clues to our common ancestor. Charles-Dominique argues that small diurnal primates would compete with diurnal birds, which explains why small primates are nocturnal, and only larger ones diurnal. This size constraint then reappears in Doyle's and Martin's treatments of allometry in brain size and developmental rates.

The reader may trace his own interests. One such might be the "psychology of place". Wilson and Rumbaugh stress that prosimians approach formal learning tests by position, not by attention to objects. Then Charles-Dominique remarks that rainforest galagos and pottos can be trapped twice running if the trap is moved to a nearby site, for "It would seem the traumatic effect of capture is associated more with the place . . . then with the trap itself". Schilling then shows how scent-marking identifies places in both individual and social contexts — again, the recourse of a more nocturnal, less visually oriented evolutionary lineage. This, in turn, ties in with the views of Pollock, Bearder, and Charles-Dominque on ranging, "detour problems" for slow-climbing forms in the forest canopy, and social organisation by the overlapping of home ranges. For many prosimians, social life itself depends on position in the forest, cued by scent marks, rather than on vocal or visual contact with other animals.

One notable contribution is Georges Pariente's study of prosimian vision. Pariente presents photography of the living retina, electrophysiological studies, measurements of light intensity in Madagascar forest conditions, and activity of nocturnal species in relation to ambient light. He argues that "nocturnal life is more a shift in thresholds of sensitivity than a completely new, 'inversed' mode of existence. The notion of a night when vision is impossible only exists for strict diurnal species . . . Nocturnal prosimians can move around perfectly well in full daylight, using their vision in the usual way". He concludes that if the prosimian eye retains this degree of plasticity, one might propose a "primate ancestor which needed to see wellby both day and night . . . small bodies, perhaps arboreal, with an appreciable amount of activity in the daytime . . . This ancestral form would have already been able to decode both in the intensity and frequency of light".

It is wholly appropriate that *The Study of Prosimian Behaviour* is dedicated to Georges Parente, who was tragically killed in a traffic accident shortly after completing his article for this book.

Alison Jolly

Alison Jolly is Research Associate in the School of Biological Sciences at the University of Sussex, Brighton, UK.

announcements

Appointments

The Royal Society has awarded a Senior Research Fellowship to **Dr D.T. Edmonds,** university lecturer in physics in the University of Oxford and fellow of Wadham College, Oxford, for five years from 1 October 1979.

Amoz I. Chernoff, has been appointed Director of the Division of Blood Diseases and Resources in the National Heart, Lung, and Blood Institute.

Dr Aksel C Wiin-Nielsen (Denmark), has been appointed Secretary-General of the World Meteorological Organization (WMO) for a period of four years commencing 1 January 1980.

Geoffrey Caston, has been appointed Secretary General of the Committee of Vice-Chancellors and Principals in succession to **Sir Roy Marshall** who is taking up the Vice-Chancellorship of the University of Hull on 1 October 1979.

The following have been elected as Junior Beit Fellows as from 1 October 1979. **Farzin Farzaneh; Simon Brian Fishel; Virginia Jane Sandford Karlsson; Andrew John Parker; John Douglas Waterfield.**

Dr Jacob A. Brody, Associate Director, Epidemiology, Demography and Biometry Program, National Institute on Aging, National Institutes of Health, has been elected Vice-President of the American Epidemiological Society.

Dr Iain M. L. Donaldson has been appointed to the Chair of Applied Zoology in the University of Hull with effect from 1 October 1979.

Dr John W. Neale of the Department of Geology, University of Hull, appointed to a personal professorship with effect from 6 April 1979.

Dr Frank M Leslie, Reader in Mathematics in the University of Strathclyde since 1971, has been appointed to a Personal Professorship of Mathematics in the University.

Professor John Stuart, has been appointed Head of a new Department of Haematology in the University of Birmingham from 1 October 1979.

Robin Butlin has been appointed professor and head of Loughborough University's Department of Geography.

Neil W. Ashcroft, professor of physics at Cornell University, has been elected director of the University's Laboratory of Atomic and Solid State Physics for a five-year term with effect from 1 July 1979.

Dr Frank Wilkinson reader in physical chemistry at the University of East Anglia, has been appointed professor of physical chemistry in Loughborough University's Department of Chemistry.

Prof Michel Revel, Head of the Weizmann Institute's Virology Department is the first incumbent of the Ruth and Jerome A. Siegel and Freda and Edward M. Siegel Chair in Virology.

Dr R.F. Sellers, has been appointed Director of the Animal Virus Research Institute in succession to **Dr J.B. Brooksby,** who retires in December 1979.

Professor Bryan E. Richards has been appointed to the Mechan Chair of Aeronautics and Fluid Mechanics in the University of Glasgow, with effect from January 1980.

Dr Christopher Arme, Principal lecturer and Head of the Biology Unit at the North Staffordshire Polytechnic, has been appointed to a new Chair of Zoology in the Department of Biological Sciences at the University of Keele, from 1 October 1979.

Meetings

15-17 August, **20th Canadian High Polymer Forum,** Quebec (Dr Ian McEwan, Secretary Treasurer, 20th Canadian High Polymer Forum, Canadian Industries Limited, 1330 Castlefield Avenue, Toronto, Ontario, Canada).

21-24 August, **Cryogenic Engineering and International Cryogenic Materials Conferences,** Madison (Mrs Dee Belsher, CEC Administrator, National Bureau of Standards, Boulder, Colorado 80303).

9-14 September, **8th International Congress on Biometerology,** Tel Aviv (World Meteorological Organization, Geneva, Switzerland).

13-15 September, **1979 Midwest Meeting of the American Geophysical Union,** Ohio Florida Avenue, N.W., Washington, D.C 20009).

17-18 September, **26th Pacific Northwest Regional Meeting,** Oregon (American Geophysical Union, 2000 Florida Avenue, N.W., Washington, D.C. 20009).

19-26 September, **World Telecommunication Forum,** Geneva (Mrs Rita Glita, American Express Travel Service, 7 rue de Mont-Blanc, Boite postale 859, 1211 Geneve 1, Switzerland).

20 September, **The Oral Cavity: Disease and Drug Treatment,** London (Secretariat, c/o Institute of Biology, 41 Queen's Gate, London SW7, UK).

23-28 September, **A short course on Computer Ergonomics,** Loughborough (J.S. Wilcox, Administrative Assistant, Department of Human Sciences, University of Technology, Loughborough, Leicestershire, UK).

26-27 September, **584th meeting of the Biochemical Society,** Swansea (Meetings Officer, The Biochemical Society, 7 Warwick Court, High Holborn, London WC1, UK).

5 October, **The Nature of the Glassy State,** London (N. Rivier, Blackett Laboratory, Imperial College, London SW7, UK).

31 October, **5th Electronics Update Colloquim,** London (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1, UK).

15 November, **Techniques of Teaching Crystallography,** London (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1, UK).

3-7 December, **1979 Fall Meeting,** San Francisco (American Geophysical Union, 2000 Florida Avenue, N.W., Washington, D.C. 20009).

18 December, **Synthetic Developments in the Prostanoid Field,** London (Secretariat, c/o Institute of Biology, 41 Queen's Gate, London SW7, UK).

1980

2-4 January 1980, **17th Annual Solid State Physics Conference,** Coventry (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1, UK).

24-26 January, **European Meeting on Intensive Care,** Paris (SOCFI, 7 rue Michel-Ange, F75016 Paris, France).

10-14 March, **1980 Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy,** Atlantic City (Frank W. Plankey, Department of Chemistry, University of Pittsburgh, Pennsylvania 15260).

17-18 March, **Modelling Dispersion of Transport Pollution,** Cambridge(The Institute of Machematics and its Applications, Maitland House, Southend-on-Sea, Essex, UK).

18-20 March, **International Symposium on the Genetic Control of Natural Resistance to Infection and Malignancy,** Montreal (Dr Emil Skamene, Montreal General Hospital, Montreal, Quebec, Canada).
24-28 March, **Vacuum Devices Conference,** Cambridge (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1, UK).
31 March-2 April, **3rd International Conference on Physicochemical Hydrodynamics,** Madrid (Prof. M.G. Velarde, Univ. Autonoma de Madrid, Cantoblanco (Madrid) Spain).
14-16 April, **Semi Insulating III-V Materials,** Nottingham (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW7, UK).
18-20 April, **1980 Annual Conference of the Education Group of the Institute of Physics,** Birmingham (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1, UK).
26-27 April, **International Symposium on Bipolymers,** Birmingham (Dr H. Warson, 284 Warwick Road, Solihull, West Midlands, UK).
26-28 April, **6th Congress of German Cybernetics Society,** Mainz (Prof. I.W. v. Seelen, Institut für Zoologie, Universität Mainz, Saarstr. 21, D-6500 Mainz, FRG).
5-10 May, **1st International Conference on the Behaviour of Marine Animals, Ecology and Pollution,** Concarneau (Dr Yves Rouger, Marine Biology Laboratory, Collège de France, Concarneau 29100, France).
6-9 May, **9th World Congress on the Prevention of Occupational Accidents and Diseases,** Amsterdam (Benelux Organising Committee, Veiligheidsinstituut, Postbox 5665, 1007 AR Amsterdam, Netherlands).
27-30 May, **Joint meeting of the Institution of Mining and Metallurgy, the Society of Mining Engineers of AIME and the Metallurgical Society of AIME,** London (The Secretary, Institution of Mining and Metallurgy, 44 Portland Place, London W1, UK).
28-31 May, **IFAC Symposium on Water and Related Land Resource Systems,** Ohio (IFAC-Water Systems 1980, American Geophysical Union, 1909 K Street, N.W., Washington D.C. 20006).
9-14 June, **9th International Symposium on Organic Sulphur Chemistry,** Riga (The Organizing Committee, Institute of Organic Synthesis of the Latvian SSR Academy of Sciences, Aizkraukles 21, 226006 Riga, USSR).
10-12 June, **2nd International Conference on Developments in Power-System Protection,** London (The Press Office, Institution of Electrical Engineers, Savoy Place, London WC2, UK).
16-20 June, **9th International Coffee Science Symposium,** London (R.J. Clarke, General Foods Limited, Banbury, Oxon, UK).
24-26 June, **International Conference on Power System Monitoring and Control,** London (The Press Office, Institute of Electrical Engineers, Savoy Place, London WC2, UK).
25 June, **Symposium on Trench and Fore-arc Sedimentation and Tectonics in Modern and Ancient Subduction Zones,** London (J.K. Leggett, Geological Society of London, Burlington House, London W1, UK).
29 June-6 July, **1980 International Palynological Congress on Diagenesis of Sedimentary Organic Matter,** Organic Preservation and Fossil Fuel Exploration, Cambridge (Dr Jim Brooks, Exploration Department, British National Oil Corporation, 150 St Vincent Street, Glasgow, UK).
21-26 June, **4th International Congress of Immunology,** Paris (Congres-Services, 1 rue Jules Lefebvre, 75009 Paris, France).
30 June-4 July, **13th International Symposium on Chromatography,** Cannes (G.A.M.S. 88 boulvard Malesherbes, 75008 Paris, France).
7-11 July, **2nd International Congress on Toxicology,** Brussels (SdR Associated, 16 Avenue de Abeilles, 1050 Brussels, Belgium).
7-12 July, **8th International Congress of Primatology,** Florence (B. Chiarelli, Institute of Anthropology, Via del Proconsolo 12, 50127 Firenze, Italy).
7-17 July, **26th International Geological Congress,** Paris (Secrétariat Général due 26eme Congrès Géologique International, Maison de la Géologie, 77-79 rue Claude Bernard, 75005 Paris, France.).
14-19 July, **9th International Conference on General Relativity and Gravitation,** Jena (Professor E. Schmutzer, GR9 Sektion Physik, Friedrich-Schiller-Universität, DDR-69 Jena, Max-Wien-Platz 1, FRG).
14-24 July, **3rd International Symposium on Water Rock Interaction,** Edmonton (Dr Brian Hitchon, Secretary-General, WRI-3, Alberta Research Council, 11315-87 Avenue, Edmonton, Alberta, Canada).
22-26 July, **4th International Conference on Cyclic Nucleotides,** Brussels (J.E. Dumont, I.R.I.B.H.N., School of Medicine, 2 rue Evers, B-1000 Brussels, Belgium).
4-9 August, **7th International Conference on Raman Spectroscopy,** Ottawa (Ken Charbonneau, Conference Services, National Research Council of Canada, Ottawa, Ontairo, Canada).
2-5 September, **7th International Symposium on Medicinal Chemistry,** Madrid (7th International Symposium on Medicinal Chemistry, 142-144 Oxford Road, Cowley, Oxford, UK).
3-5 September, **Microbial Adhesion to Surfaces,** Reading (Dr P.R. Rutter, c/o The Conference Secretariat, Society of Chemical Industry, 14 Belgrave Square, London SW1, UK).
5-7 September, **17th Symposium of European Association against Virus Diseases,** Munich (Professor F. Deinhardt, Max-von-Pettenkofer-Institut, Pettenkoferstrabe 9a, D-8000 München 2, FRG).

newly on the market

Conversion master. The Decimo Goldfinger conversion master gives instant conversion of measures of length, area, volume and temperature into and from their metric equivalents. This new liquid crystal display model, which has all the standard calculator functions, including full 'live' memory, comes complete with its own wallet.
Circle No. 84 on Reader Enquiry Card.

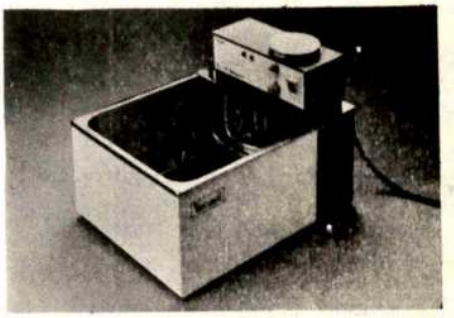
The Life Science hydraulic press

Hydraulic press for cell disintegration. Life Science Laboratories have introduced a 16-ton hydraulic press for use with the Biox X-Press cell disintegration equipment. This unit has been modified for use with the 5 and 25 ml X-Press models. The X-Press system operates at -20°C and gurantees a high percentage breakdown of even the toughest cell walls. The low temperature and method of disruption protect the cell contents from damage and deterioration, while the compact, lightweight design of the press enables the equipment to be used anywhere.
Circle No. 85 on Reader Enquiry Card.

Protein Assay. Bio-Rad Laboratories have introduced the protein assay kit II, which is a 5-min, single reagent, dye-binding technique that is easily automated and has none of the interference characteristics inherent in the Lowry and Biuret tests. The kit contains bovine plasma albumin as a standard reference protein. Protein assay kit I has not changed and uses bovine γ globulin as a protein reference. The kits are available complete or as separate component reagent or standards.
Circle No. 86 on Reader Enquiry Card.

These notes are based on information provided by the manufacturers. For further details circle the appropriate numbers on the Reader Enquiry Card bound inside the cover.

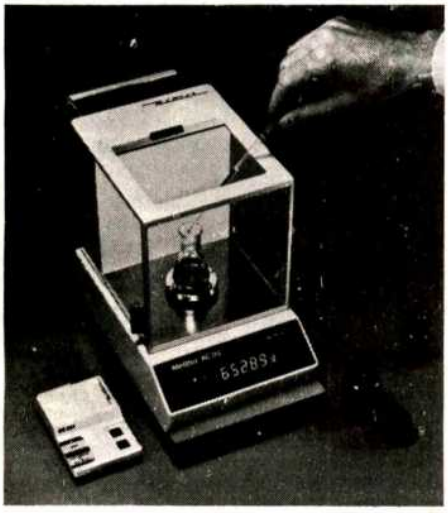
Blood separation. Histopaque from Sigma London is a new cost-saving multiple pack (size 12 × 100 ml) of Histopaque-1077. Histopaque-1077 is an inexpensive reagent that readily effects the separation of mononuclear leukocytes from whole blood without significant cell damage. It is packed in 100-ml bottles. The reagent is quite stable and may be stored in a refrigerator for at least 12 months without deterioration.
Circle No. 87 on Reader Enquiry Card.



Microscope slide engraver. Temtool have introduced a diamond engraver for marking glass. The engraver is powered by a 12-V mains transformer and is automatically switched on when inclined to a writing position. A rotating diamond tip is held in a pen-like drive unit made from aluminium — all electrical and moving parts are sealed from solvent attack.
Circle No. 88 on Reader Enquiry Card.

Blood storage refrigerator. Forma Scientific has introduced a new line of giant capacity blood storage refrigerators designed for blood bank use. The 48 cu. ft blood bank unit protects up to 660 plastic bags of whole blood at a precise +4°C operating temperature. The exclusive Forma 'ringback' alarm is designed with normal and standby modes to monitor normal operation, pulldown and recovery. All models feature stainless steel roll-out drawers, automatic defrost and internal condensate removal and a pressure-writing temperature recorder. Standard dimensions are 54.75″ wide × 35.5″ deep × 83.125″ high.
Circle No. 89 on Reader Enquiry Card.

Automated Stat/routine analyser. Beckman. The Astra 8 Analyzer is a free-standing, computer-controlled chemistry analyser that accommodates eight analytical modules. In a common six-module configuration, the system gives glucose, BUN, creatinine, sodium, potassium, chloride and CO_2 determinations, plus calculated osmolality, BUN/creatinine ratio and anion gap values. All the necessary controls are clearly identified for easy instrument operation. Any or all of the individual tests for each patient sample or up to two trays — 80 samples — can be selected at one time for walk-away operation. Up to 80 samples can be run per hour by selecting individual tests for each sample. Throughput for routine, or run-all, determinations is typically greater than 60 samples per hour.
Circle No. 90 on Reader Enquiry Card.



Fibre optic light detector. Life Science Laboratories have recently added a fibre optic light detector to their QSM 2500 Quanta spectrometer. The QSM is a portable instrument capable of scanning the visible wavelengths and recording the number of quantum units per m^2 per s per nm. The flexible fibre optic head enables measurement in a restricted space. The complete instrument is battery powered and a new optional field housing makes carrying easy and ensures protection from mud and moisture. Further options include a mains power supply, an underwater housing for marine applications and an integrator module capable of measuring the total energy falling over all or part of the spectrum.
Circle No. 91 on Reader Enquiry Card.

Constant temperature baths. Techne. Two new series of constant temperature baths are now available from Techne. The TE Series is the standard choice for the laboratory, while the TU Series is the ultimate for very fine temperature control. They cover temperature ranges from -40°C to +180°C. The TE Series is based on the recently introduced Tempette thermoregulator. The baths have a temperature stability of ± 0.02°C, offer fine control and are easy to use. The TU Series is based on the Tempunit thermoregulator — features include three preset controls and temperature stability of ± 0.005°C.
Circle No. 92 on Reader Enquiry Card.

The Techne EU Series

Luminometer. The Packard Instrument Company announces the introduction of the Pico-Lite, a microprocesor-controlled luminometer which measures light produced in bio- and chemiluminescent reactions. The Pico-Lite determines ATP by using the luciferin–luciferase system of the firefly. The instrument can be operated at temperatures above or below ambient and it has a detector system that can store up to six samples.
Circle No. 93 on Reader Enquiry Card.

Top-loading balance. Mettler. The AC88 top-loading balance from Mettler is a balance capable of performing complicated analytical weighing by the simple touch of a single control bar, also featuring the Mettler Deltarange, which gives an extremely accurate fine range. This additional facility allows up to 8 g to be weighed to 0.1 mg anywhere within the overall range of 80 g. If the fine range is exceeded during weighing the balance can be tared by pressing the control bar, which brings the Deltarange back into play and weighing starts again. The AC88 is suitable for individual as well as serial weighings and as a prescription balance.
Circle No. 94 on Reader Enquiry Card.

The Mettler AC88

Automated gel permeation chromatography system. An automated data reduction system is available from Perkin-Elmer. Offered as a complete hardware and software package or separately, the gel permeation chromatography system includes: Series 1 LC pump, LC-100 column oven, a selection of GPC columns, sigma 10 data station, gel permeation chromatography software and complete user instructions. The new system automates manual procedures associated with gel permeation chromatography, and assures instant, precise results.
Circle No. 95 on Reader Enquiry Card.

Analytical balance. The Torsion Balance Company has introduced the Torbal SEA-1, a compact analytical balance specifically designed for university and school laboratory use. It features 160-g weighing capacity, 0.1-1 mg accuracy, electronic null indication and full digital display to 159.9999 g. The new balance contains several design and control features that make it especially suited for use in educational applications. Unknown weight quantities can be determined simply by turning control knobs until the needle of the null indicator rests at zero. The weight — shown to 4 decimal places — is displayed in digital form. No vernier or micrometer adjustments are required.
Circle No. 96 on Reader Enquiry Card.

Sound power calculator. B & K Laboratories have announced a new sound power calculator for the determination of sound power levels to the most rigorous national and international standards. The 7507, as it is known, averages sound pressure levels over a selected time interval and adds to them a room correction term to yield the sound power level. The introduction of the adjustable room correction term means that measurements can be performed in both reverberant and anechoic environments. The sound pressure and sound power levels are indicated on the digital display as A-weighted levels or as octave or third-octave band levels over the frequency range of 100-10 kHz, and if required these results can be read out via the digital or analogue output. The 7507 has built-in interface for IEC standard bus, allowing output in either 'addressable' or 'talk only' modes.
Circle No. 97 on Reader Enquiry Card.

Adjustable flatness polishing plates. Logitech have introduced a range of lapping and polishing plates incorporating a wholly new design feature which allows plate curvature to be adjusted by simply turning a screw. The Logitech plates substantially reduce initial conditioning time and allow subsequent curvature modifications to be performed in seconds. The plates are available in a variety of materials including cast iron, tin, lead, solder and wax. They are available in 200 mm and 300 mm diameter sizes to fit Logitech PM2, PM2A and LP30 machines.
Circle No. 98 on Reader Enquiry Card.

Microprotein Rapid Stat Kit. Pierce. The new Pierce Microprotein Rapid Stat Kit is the first commercially available test for the accurate determination of low levels of protein in biological fluids. The reagent uses the highly protein-sensitive dye Coomassie brilliant blue (CBB) G250. The dye binds to the protein causing a change in its optical properties. The dye–protein complex absorbs strongly at 610 nm, where it is colorimetrically evaluated. The CBB G250 will bind with almost the same affinity to the wide variety of proteins found in serum, CSF or urine. Advantages of the kit include no precipitating or centrifugation needed; single, stable colorimetric reagent; quantitative results obtained in 20 min at 37° C; can measure undiluted CSF protein to 100 mg dl^{-1} and undiluted urine protein to 10 mg dl^{-1}.
Circle No. 99 on Reader Enquiry Card.

Disposable dust respirator. Racal Safety. Dustopper, from Racal, is a disposable dust respirator which can be worn with comfort by workers in dusty environments. The respirator can be folded flat and put in a pocket when not in use, and is easily fitted over a wearer's mouth and nose.
Circle No. 100 on Reader Enquiry Card.

Dispersion-consolidated platinum. Degussa. The high strength values of the dispersion-consolidated platinum available from Degussa remain unchanged at temperatures of over 1,000°C, and allow considerable savings in comparison with pure platinum because of the longer service life of the components or the reduction of weight while retaining dimensional stability. The high thermal resistance and creep strength of dispersion-consolidated platinum at high temperatures are due to the small amounts of finely dispersed zirconium oxide that are added to the metal to stabilise the platinum matrix. The ductility of the material allows hot or cold shaping by conventional methods. Even machining of the material, which has the same corrosion behaviour as pure platinum, presents no difficulties.
Circle No. 101 on Reader Enquiry Card.

Bichromatic analyser. The Abbott VP is a fast and easy to use automated chemistry system featuring advanced microprocessor technology. Procedures are automatically programmed with capability for easy operator changes or reprogramming of additional user defined methods. Maximum throughput is 465 substrate tests h^{-1} or 310 rate tests h^{-1}. Average instrument analysis time is rapid with an average of 5.5 min for 30 samples of an individual test. Operator involvement is minimal, dispense system washing and priming are automatic, test changeover rapid. Average sample requirement is less than 10 μl per test with a reagent volume of only 250 μl per test.
Circle No. 102 on Reader Enquiry Card.

The Abbott VP bichromatic analyser

X-Ray spectroscopy system. Tracor Northern. The TN-2000 X-ray spectroscopy system from Tracor Northern performs quantitative analysis for elements $z = 10$ to 99. Programmable operation is offered with a number of field-proven data reduction and analysis routines. The system is equipped with an LSI-11/2 microprocessor and a PDP-11 type miniprocessor can be substituted for greater CPU power. Available options for system upgrade include floppy disc, mag tape, printers, plotters and teletype.
Circle No. 103 on Reader Enquiry Card.

APPOINTMENTS VACANT

INSTITUTE OF CANCER RESEARCH

A GRADUATE

who has had several years experience of computing or completed a project with extensive computer usage is required to work on real time data processing on a PDP 11/70 using MUMPS.

The post would be for 2½ years in the first instance and suitable for someone completing a higher degree this year. It would be established on the Institute's Scientific Scale II in the range £4,261 to £5,591 p.a. plus London Allowance of £502 p.a. according to age and experience.

The successful applicant would work in close co-operation with the staff of the Royal Marsden Hospital both at Fulham Road and at Sutton, Surrey.

Applications in duplicate with the names of two referees should be sent to the Secretary, Institute of Cancer Research, 34 Sumner Place, London, SW7 3NU, quoting ref. 300/G/12. 2856(A)

THE MEDICAL COLLEGE OF WISCONSIN, INC.

BIOCHEMIST OR CELL BIOLOGIST

I am looking for 2 imaginative scientists with interest and enthusiasm to study interaction of interferon with cell membranes. This project is funded by a three-year grant from NIH and provides for two positions, one at a postdoctoral level (appr. $13,000 per annum), the other at a lower level, which will pay somewhat less. Thus, persons with PhD, MD, MSc or equivalent training or experience will be considered. The College provides fringe benefits and the atmosphere in a diversified biochemistry department is stimulating and cordial. We recently moved into brand-new and well-equipped facilities.

Please send enquiries to Dr Helmut Ankel, Department of Biochemistry, Medical College of Wisconsin, PO Box 26509, Milwaukee, Wisconsin 53226. W288(A)

UNIVERSITY OF LONDON KING'S COLLEGE

DEPARTMENT OF ANATOMY

Applications are invited for an

MRC POSTDOCTORAL RESEARCH ASSISTANT

in

DEVELOPMENTAL NEUROBIOLOGY

to work on the development of limb innervation in the chick embryo. Experience in electrophysiology and/or developmental biology would be an advantage.

The post will be available from 1st October 1979 for up to 3 years, salary in the range £4,333 to £4,910 p.a. plus £502 p.a. London Allowance.

Applications, together with c.v. and names of two referees, to: Dr J.H. Lewis, Department of Anatomy, King's College, Strand, London WC2R 2LS as soon as possible, quoting 191689/ 2858(A)

UNIVERSITY OF LEICESTER

DEPARTMENT OF GENETICS

POST-DOCTORAL RESEARCH ASSISTANT

Applications are invited for a post-doctoral research appointment supported by the Medical Research Council to study plasmid controlled iron-uptake in *Escherichia coli* as part of a group working on virulence determinants of bacterial strains pathogenic for man. The position is available from 1st October 1979, and is for up to 3 years. The salary will be on the Research Support Scale 1A, plus superannuation.

Applications, with curriculum vitae, and the names of two referees, should be addressed to Dr P.H. Williams, Department of Genetics, University of Leicester, University Road, Leicester LE1 7RH. 2879(A)

THE AUSTRALIAN NATIONAL UNIVERSITY

Research School of Biological Sciences

DEPARTMENT OF POPULATION BIOLOGY

RESEARCH FELLOW

Applications are invited from suitably qualified persons for appointment to the above-mentioned position.

The Department is expanding the area of molecular cyto-genetics, specifically genome structure and evolution in eukaryotes. Current interests encompass genetic and molecular studies on DROSOPHILA and rodent genomes, with special emphasis on highly repeated DNA. Applicants should have postdoctoral experience, be familiar with chromosome manipulation in DROSOPHILA and have a desire to develop a programme which includes molecular and genetic approaches to eukaryotic genome structure.

Closing date 14 September 1979.

Salary will be in accordance with qualifications and experience within the range $A16,291 to $21,265 per annum. Present exchange rates are $A1 = 50p = $US1.12.

Term of appointment: three years in the first instance with the possibility of extension to five years.

Other conditions: reasonable appointment expenses are paid. Superannuation benefits are available for applicants who are eligible to contribute. Assistance with finding accommodation is provided for an appointee from outside Canberra. The University reserves the right not to make an appointment or to make an appointment by invitation at any time.

Prospective applicants should first obtain further particulars from the Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF. 2837(A)

UNIVERSITY OF AUCKLAND

New Zealand

GEOGRAPHY TEMPORARY FULL-TIME LECTURESHIP

Closing date 28 September 1979.

Applications are invited from specialists in any branch of physical geography, although an interest in instrumentation, laboratory and field techniques would be an advantage. The appointment is available for three years from 1 February, 1980 to 31 January 1983.

GEOTHERMAL INSTITUTE SENIOR LECTURESHIP/ LECTURESHIP

Closing date 14 September 1979.

Applications are invited from Professional Engineers. Applicants must have a strong academic background in Chemical, Civil or Mechanical Engineering, or in Engineering Science, knowledge and experience of one or more aspects of geothermal technology; and be prepared to lecture on those aspects of geothermal technology in which they have specialist knowledge.

Commencing salaries in accordance with qualifications and experience will be established within the range for Lecturers or Senior Lecturers, at present NZ$11,529 to $16,780 per annum. At present all salaries are supplemented by a General Wage Order of NZ$365 per annum. Conditions of Appointment and Method of Application are available from the Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF. Applications, in accordance with 'Method of Application', should be forwarded as soon as possible but not later than the closing dates stated. 2839(A)

HEAD OF IMMUNOLOGY SECTION

Applications are invited for the post of Scientific Head of a new Section of Immunology in the Institute. The main functions of the Institute are the standardization and statutory control of biological substances used in human medicine, work which is well supported by research. It has been decided to form this new Section to assume responsibility for standardization, control and research in immunology, and to provide immunological support to the other Institute departments. The Section will also incorporate the Institute's existing work in the field of allergens.

The post calls for the ability to undertake independent and collaborative research and to lead a small group of staff. Applicants should be experienced in laboratory immunology and research.

Salary will depend on experience and age and is likely to be in the Senior or Special Appointments Grades.

Further details of the post are available from the Personnel Officer, National Institute for Biological Standards and Control, Holly Hill, Hampstead, London NW3. Telephone 01-435 2232 Extension 200, quoting reference IM/208.

NIBSC

National Institute for Biological Standards and Control

2822(A)

Ministry of Agriculture, Fisheries and Food, Food Science Division

CHEMIST/BIOCHEMIST

London

. . . to join a multi-disciplinary team which provides a wide range of scientific advice to those responsible for legislation on all aspects of the manufacture, composition and use of food additives. The post involves work on colouring matters, clouding agents and enzymes used in food preparation, and includes close liaison with industry and other Government Departments which have responsibilities for food composition and safety.

The successful candidate will also participate in the Scientific Secretariat of the UK Food Additives and Contaminants Committee and assist in the implementation of the Committee's recommendations by revised or new legislation. The work includes preparing papers and briefs for use at international meetings and, after training, attending internal meetings especially in relation to the negotiations of EEC Directives on food additives. No laboratory work is involved with this post.

Candidates (normally aged under 32) should have a good honours degree in chemistry, biochemistry or a closely related science and should have at least 4 years' postgraduate experience. A working knowledge of food technology or the chemical manufacturing industry would be an advantage. Appointment as Senior Scientific Officer. *Ref SB/39/AE.*

CHEMIST

London

. . . to undertake the chemical analysis of such foods as flour, dried skim-milk, sugar, fat and biscuits both initially and during storage. Tests include moisture, protein, reducing sugars, fat content and fat rancidity parameters. An important aspect of the work will be the introduction of modern instrumental techniques and the development and application of new methods.

Candidates (normally aged under 27) should have a degree or equivalent in chemistry or food science. An interest in analysis would be an advantage. Appointment as Scientific Officer. *Ref SB/40/AE.*

CHEMIST

Norwich

. . . to join a team studying both potentially hazardous and nutritionally important trace elements in food. Work includes special surveys, analytical method evaluation and development, collaborative trials and metal speciation studies in foods. Atomic absorption and plasma emission spectrometry techniques are used extensively together with polarography, anodic stripping voltametry and gas and high pressure liquid-chromatography.

Candidates (normally aged under 27) should have an honours degree in chemistry. Some analytical laboratory experience would be an advantage. Appointment as Scientific Officer. *Ref SB/41/AE.*

Salary: Senior Scientific Officer £6,400 to £8,385; Scientific Officer £3,810 to £5,605; (to become £6,855 to £9,225 and £4,115 to £6,010 respectively from 1.1.80). Salary £524 less in Norwich. Starting salary according to qualifications and experience. Promotion prospects. Non-contributory pension scheme.

These posts have been exempted from the Government's ban on recruitment

For further details and an application form (to be returned by 3 September 1979) write to Civil Service Commission, Alencon Link, Basingstoke, Hants, RG21 1JB, or telephone Basingstoke (0256) 6k8551 (answering service operates outside office hours). *Please quote appropriate reference.* 2878(A)

SENIOR RESEARCH ASSISTANT/ RESEARCH ASSISTANT

Applications are invited from suitab qualified candidates with experience biochemistry and microbial genetics for tl vacancies of **Senior Research Assistant a Research Assistant** in the **Department Genetics.** The successful candidates will jo an SRC funded project on DNA repa activity in yeast cells. Applications for tl Senior Research Assistant should have a Ph degree or be about to submit for such degree.

The appointments will be for two yea from 1 October, 1979 and will be on tl following salary scales.

Senior Research Assistant: Commenci salary up to £4,910 per annum plu USS/USDPS benefits.

Research Assistant: Commencing sala £3,775 per annum plus USS/USDF benefits.

Informal enquiries may be made to Dr J Parry in the Department of Genetics, b further particulars and application forn (two copies) may be obtained from tl Personnel Officer, University College Swansea, Singleton Park, Swansea, SA 8PP, to whom they should be returned l *1 September, 1979.* 2871(A)

UNIVERSITY OF SOUTHAMPTON

LECTURER IN CRYOGENICS

Applications are invited for the post

LECTURER

in the newly-formed Cryogenics Grou in the Faculty of Engineering ar Applied Science.

Candidates should have an acti research interest in the application low temperatures and wide experien with cryogenic fluids and associate instrumentation. The perso appointed will be expected to intera effectively with the group and play full part in the postgraduate trainir activities.

Salary scale:- £4,333 to £8,992 p annum (under review). The initi salary will depend on qualificatio and experience.

Further particulars may be obtaine form D.A.S. Copland, Th University, Southampton SO9 5NH whom applications (7 copies fro U.K. applicants) should be sent n later than 17 September 1979. Plea quote reference 215/A./Na.2876(A)

THE UNIVERSITY OF MELBOURNE

CHAIR OF VETERINARY BIOLOGY

Applications are invited for appointment to the Chair of Veterinary Biology. The Chair has been established to give academic leadership in the Department of Veterinary Preclinical Sciences and the University will consider applications from persons appropriately qualified in Veterinary Anatomy, Physiology or Pharmacology.

Salary: $A34,119 per annum.

Further information, including details of application procedure, superannuation, travel and removal expenses, housing assistance, and conditions of appointment is available from the Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF.

Applications close on *26 October 1979.* 2860(A)

UNIVERSITY OF NOTTINGHAM

DEPARTMENT OF OBSTETRICS & GYNAECOLOGY

Applications are invited for the post of

RESEARCH ASSISTANT

to join a group working on the renin-angiotensin system in pregnancy. Candidates should hold a good honours degree in Biochemistry, Physiology or a related subject. The successful candidate will be expected to register for a PhD degree.

The appointment is for 3 years at an initial salary of £3,775 (£4,333 if 26 or over).

Applications, with curriculum vitae and names of three referees, should be sent by 3rd September 1979 to Dr F. Broughton Pipkin, Department of Obstetrics and Gynaecology, City Hospital, Hucknall Road, Nottingham. 2855(A)

UNIVERSITY OF OTTAWA

DEPARTMENT OF BIOCHEMISTRY

POSTDOCTORAL RESEARCH ASSISTANTS

Two recent PhD graduates required to join research group working on plant protein utilization. An enzymologist with experience preferably in cereal chemistry or plant physiology is needed for characterization of lipase in high-protein oats during maturation and storage. A microchemist experienced in stain development is needed to study localization of phytate, glucosinolates, etc. in rapeseed. Research involves collaboration with the food industry and the Food Research Institute of Agriculture Canada. Salary minimum $12,200.

Please apply to Dr I Altosaar, Biochemistry Dept, University of Ottawa, 40 Somerset Street East, Ottawa, Ontario K1N 6N5 Canada. W287(A)

UNIVERSITY OF ST ANDREWS

DEPARTMENT OF ZOOLOGY

Applications are invited for the post

POSTDOCTORAL RESEARCH ASSISTANT

(Molecular Biology)

to work in collaboration wi Dr J Sommerville on an investigation of t packaging and processing of RNA tra scripts in eukaryote cells. Applicants shou have a training in biochemistry or micr biology. Experience in nucleic acid biochei istry or the electron microscopy of nucle acids would be an advantage. The appoir ment is for up to 3 years, starting date arrangements, and is supported by the SR Starting salary within range 1A £4,333 £4,910 (under review), plus FSSU/US Informal enquiries may be made Dr J Sommerville (Tel: St Andrews 72823

Applications (two copies preferably typescript), with the names of two refere should be lodged by **12th September 19** with the Establishments Officer, Tl University, College Gate, St Andrews, Fi KY16 9AJ. 2832(A)

British Museum (Natural History)

Editorial Assistant

The Museum is replacing the existing exhibition by a completely new scheme designed to present an integrated view of modern biology. The Editorial Assistant, as a member of a team, will collaborate with the biologists and designers who are devising the exhibits to ensure that all exhibition labels, texts, commentaries and associated publications are written in simple attractive everyday language.

Candidates should normally be aged under 27 and have a degree or equivalent in a biological science. They should also have a sound biological background. A genuine interest in communicating scientific ideas to others would be advantageous.

Appointment will be as Scientific Officer. Starting salary (according to qualifications and experience) within the range £3,810 to £5,605 (to become £4,115 to £6,010 from 1.1.80).

For further information and an application form (to be returned by 4 September 1979) write to Civil Service Commission, Alencon Link, Basingstoke, Hants, RG21 1JB or telephone Basingstoke (0256) 68551 (answering service operates outside office hours). **Please quote ref: SB/59/DK.** 2844(A)

UNIVERSITY OF BIRMINGHAM

HEMICAL ENGINEERING RESEARCH FELLOW

ıplications are invited for a Research llow in Biological fouling film formation d removal, to be a member of a team 'estigating the biological fouling of heat :hanger surfaces, for a period of two ars.

This involves the mechanisms of laying wn, adhesion and removal of biological uling films on surfaces, and the crobiology of the deposits. The Fellow ll also act as an advisor on microbiologist a biochemist/biochemical engineer with sound understanding of the ndamentals of microbiology.

The Fellow will be based at AERE ırwell, where the Heat Transfer and uid Flow Service is sponsoring an overall oject on the fouling of heat exchanger ınt. The appointment is subject to the rmal security arrangements presently in rce at Harwell.

Salary will be in the RF1A range £4,333 £7,521, plus superannuation. Maximum ırting salary will be £5,777. Starting date as soon as can be arranged.

Further particulars are available from e Assistant Registrar, Science and ıgineering Registry, University of rmingham, PO Box 363, Birmingham 5 2TT, to whom applications including ll curriculum vitae (3 copies), and naming ree referees, should be sent by Friday th August 1979. Please quote ref NT9.

2820(A)

UNIVERSITY OF HEIDELBERG

EPARTMENT OF NEUROBIOLOGY

research worker with experience in ctron microscopy, preferentially of the rvous system, is required for supervision the newly established electron croscopy unit in the department. ɔplicants should be interested in velopmental neurobiology and willing to rticipate in ongoing immunological, cell ological and electrophysiological ɔjects. The level of the position is flexible pending on background and alifications.

Applications with curriculum vitae and mes and addresses of three referees ɔuld be sent to Dr M Schachner, Dept of :urobiology, Heidelberg University, Im :uenheimer Feld 347, D-6900 :idelberg, West Germany. W277(A)

THE QUEEN'S UNIVERSITY OF BELFAST

RESEARCH ASSISTANT

MARINE BIOLOGY

Research Assistant required to continue a biological study of the shore in the vicinity of the new oil-fired power station at Kilroot commissioned by the Northern Ireland Electricity Service. The post to commence as soon as possible is tenable for approximately three years. Candidates must have a degree or equivalent qualification in an appropriate biological subject. Commencing salary in the range £3,690 to £4,233 per annum (under review).

Further particulars may be obtained from the Personnel Officer, The Queen's University of Belfast, BT7 1NN, Northern Ireland, to whom application should be made enclosing a full curriculum vitae and the names and addresses of two referees. Closing date 15th August, 1979. 2825(A)

UNIVERSITY OF EDINBURGH DEPARTMENT OF PATHOLOGY

RESEARCH FELLOW IN RESPIRATORY PATHOLOGY

A post-doctoral Research Fellow with a biological background is required to work on the structural and functional abnormalities of the lung in chronic bronchitis. Previous experience of histology and quantitation morphology desirable.

Salary from £4,232 pa. Starting date — October 1st, 1979.

For further details contact Dr D Lamb, Department of Pathology, University of Edinburgh, Teviot Place, Edinburgh, EH8 9AG (031 667 1011 ext 2262/2275). The closing date for applications is 28th August, 1979. Please quote reference 5044.

2834(A)

SCIENTIFIC/MEDICAL EDITOR

Medical foundation in central London needs an editor to prepare the proceedings of biomedical conferences for publication. Previous experience of manuscript editing desirable. A good honours degree in physiology/biochemistry/zoology (or a combination of these) is essential, as is a flair for language, an eye for relevant detail and the ability to deal tactfully with authors. Pleasant working conditions, with own office, free lunch, four weeks' holiday. Salary in scale £4,370 to £6,141. Age 25-35.

Please write, with full c.v., to
Senior Editor, Ciba Foundation, 41 Portland Place, London W1N 4BN

2863(A)

LUDWIG INSTITUTE FOR CANCER RESEARCH (LONDON BRANCH)

(in association with the Royal Marsden Hospital and the Institute of Cancer Research, Sutton, Surrey)

RESEARCH OFFICER

The Ludwig Institute for Cancer Research (established in Zurich in 1971) maintains branches located in England, Switzerland, Australia and Belgium. The London Branch is located at Sutton, Surrey and, in association with the Royal Marsden Hospital and Institute of Cancer Research, is engaged in a research programme focussed particularly on aspects of breast disease, both clinical and fundamental.

The Unit of Molecular Biology, now under active formation, will undertake basic research into breast cancer and requires a RESEARCH OFFICER who will be involved in the maintenance of cultured cell lines and in their biochemical characterisation.

Candidates for this appointment should have had two years or more post qualification relevant experience of tissue culture and biochemical techniques to qualify for appointment within the salary scale £3,582 to £4,902 plus LW. Applications from less qualified candidates who nevertheless possess suitable experience will also be considered for appointment within the Technician grade £3,261 to £4,680.

Apply with full particulars and names of two referees to The Secretary, London Branch, Ludwig Institute for Cancer Research, Clifton Avenue, Sutton, Surrey SM2 5PX.

2809(A)

Vacancies in Drug Metabolism

The following vacancies exist in the Department of Drug Metabolism and Pharmacokinetics at the Hoechst Pharmaceuticals Research Laboratories in Milton Keynes.

Senior Scientist

The successful candidate will lead a small team of scientific and technical staff investigating the metabolic fate of candidate drug compounds in animals and man.

The work for which a Ph.D. in Biochemistry, Pharmacology, Chemistry or an associated discipline is essential, would require a scientist with several years experience in this field, preferably in industry.

Scientist

The position would be ideally suited to a Ph.D. who has just graduated in one of the above mentioned disciplines, or Graduate with some experience within the area of drug metabolism.

Technician

A vacancy also exists for a Technician who would assist a Ph.D. Scientist in metabolic experiments. Minimum qualifications would be HNC, 'A' levels or equivalent. Further education would be encouraged. Graduates would also be considered for the position.

All positions carry first-rate salaries. Benefits include at least four weeks holiday a year, flexible working hours, generous pension scheme and private health scheme. Relocation expenses would be paid where appropriate.

Please write or telephone for an application form to:
Sheila Matthews, Personnel Department, Hoechst UK Limited, Walton Manor, Walton, Milton Keynes, Bucks.
Tel: Pineham 5068

Hoechst

2813(A)

THE OPEN UNIVERSITY

FACULTY OF SCIENCE

POST-DOCTORAL RESEARCH FELLOW IN ISOTOPE GEOLOGY (TEMPORARY)

Applications are invited for the above pos from candidates with an honours degree, doctorate, and several years experience i operating mass spectrometers, preferably i the geological sciences. In cases of prove expertise applications will be considere from candidates without a higher degree The Department of Earth Sciences ha recently purchased the latest VG solid sourc mass spectrometer (Isomass 54E) which wi be commissioned shortly when work on th isotope laboratories is complete. Th successful applicant will work closely with D C J Hawkesworth but will be encouraged t initiate new projects, develop techniques an be responsible for the day to day running o the isotope laboratories.

Appointment will be from the earlies convenient date for a period of three years i the first instance, on the salary scale £4,23 to £7,145 pa.

Further information can be obtained fron The Secretary, Department of Eart Sciences, Open University, telephone 090 63012.

Application forms and further particular are available, by postcard request please from The Recruitment Office (JD3915/1) The Open University, PO Box 75, Walto Hall, Milton Keynes, MK7 6AL or telephon Milton Keynes 63404: there is a 24 hou answering service on 63868.

Closing date for applications: 23rd August 2868(A)

THE UNIVERSITY OF LEEDS

DEPARTMENT OF MICROBIOLOGY

Applications are invited for a post of **RESEARCH FELLOW** in the above Department. Candidate should already possess, or expect to b awarded, a PhD degree. Th appointment will be made for a fixe period of three years with effect from January 1980.

The successful applicant will work under the direction of Dr P.W. Taylo and will take part in a research projec on the biosynthesis of surface antigens associated with the virulence o *Escherichia coli*. The work is financed by the M.R.C. An individual wit experience of continuous culture and/or biochemical techniques for the analysis of Gram-negative cell surface components would be preferred.

Preliminary enquiries may b directed to Dr P.W. Taylor Department of Microbiology, The University, Leeds LS2 9JT (Telephone (0532) 36171 ext. 145).

Starting salary in the range £4,333 t £4,910 on the IA scale for Research and Analogous Staff (£4,333 to £7,521 (under review).

Curiculum vitae and the names o three referees should be sent to the Registrar, The University, Leeds LS2 9JT, quoting reference numbe 96/14/D. Closing date for applications 1 October 1979. 2877(A)

TECHNICIAN/ RESEARCH OFFICER

required by our Medical Oncology Unit at S Bartholomew's Hospital to assit wit cytogenic studies on human leukaemia an lymphoma. Experience of tissue culture an banding techniques an advantage Degree/HNC. Salary range £3,650 to £5,256

For further information and applicatio form telephone or write to Miss S M Hurley Imperial Cancer Research Fund, Lincoln' Inn Fields, WC2 on 242 0200 ext 305, quotin reference 348/79. 2866(A)

PROFESSOR AND CHAIRPERSON, Microbiology. A major state university seeks applicants for head of its Department of Bacteriology and Immunology in the School of Medicine. Selection criteria will include evidence of: leadership ability; broad interests in medical and paramedical teaching at graduate and undergraduate levels; scientific achievement; state/national/international endeavours in the field; and compatability with the philosophy of a well-established, dynamic department. Interested parties should submit enquiries or letters of application with curriculum vitae and references to Wallace A. Clyde Jr, MD, Search Committee Chairperson, Department of Paediatrics, 535 Burnett-Womack Building 229-H, University of North Carolina, Chapel Hill, North Carolina 27514. (An affirmative action/equal opportunity employer). W290(A)

University of Riyadh, Saudi Arabia

Medical Faculty

Applications are invited from suitably qualified men and women to fill posts as Professors, Associate Professors, Assistant Professors, Lecturers and Demonstrators in the Preclinical and Clinical Subjects and Related Studies as indicated below for the academic year 1979/1980. Applicants should have higher qualifications and teaching experience at University level.

Anatomy	**Associate Professors; Assistant Professors; Demonstrators**
Physiology	**Professor; Associate Professors; Assistant Professors; Lecturers**
Biochemistry	**Professors; Associate Professors; Assistant Professors; Lecturers; Demonstrators**

Salary Scales: **Monthly in Saudi Ryals (SR7·7=£1, approx.)**

	Basic monthly salary	Annual Increment (Monthly)	Maximum monthly salary
Professors:	**6 595**	**400**	**8 995**
Associate Professors:	**5 835**	**350**	**7 585**
Assistant Professors:	**4 695**	**315**	**7 215**
Lecturers:	**3 385**	**300**	**5 685**
Demonstrators:	**2 785**	**250**	**4 780**

(Associate Professor and Assistant Professor are equivalent to Senior Lecturer and Lecturer respectively in the U.K.)

Consideration will be given to increases of up to 100% on the monthly salaries quoted above for candidates who have been or are holders of academic posts equivalent to those for which they are applying or who have been and are engaged in teaching at University level.

Appointments are normally for one year and renewable.

Clinical Allowance – For those engaged in clinical care of patients in hospital there is an allowance at the rate of 80% of the basic salary. For medically qualified staff not engaged in clinical care of patients there is a *Professional Allowance* at the rate of 30% of basic salary.

Free furnished accommodation or if not available a housing allowance and installation grant. Terminal gratuity, local transport allowance and annual leave passages for incumbent and up to three dependents are paid. There is no income tax in Saudi Arabia and money is freely convertible and transferable.

Application with a comprehensive c.v. and names and addresses of two referees to be sent to: Dr. Hassan Kamel M.R.C.P., The Dean, Medical Faculty, P.O. Box 2925, Riyadh, and at the same time four copies of application and c.v. with names and addresses of referees to be sent to Dr. A.T.G. Johnston, c/o London School of Hygiene and Tropical Medicine, Keppel Street, London WC1E 7HT, who will send further details on request. **Closing date – 23rd August, 1979. There are no special application forms.**

plications are invited for the post of

SENIOR TECHNICAL OFFICER

in the

DEPARTMENT OF BIOLOGY

e appointee will take charge of the partments Teaching Museum which rently has in excess of 18,000 specimens. sponsibilities include the care and velopment of the reference and teaching lection; preserving; mounting and play of biological specimens, as well as wing, modelling and photography. The ointee will also be responsible for some the day to day running of courses. cial emphasis is given on the ability of ervising and training junior technical ff. Applicants should have relevant loma or certificate and several years erience in an educational institution. ary scale: K10,165 pa (£1 sterling £1.61). Family passages; baggage wance; 3 year appointment; 24% tuity of which 2% is taxable; rent-free ommodation; overseas leave; education wances; medical aid scheme.

Detailed applications (2 copies) with riculum vitae and naming 3 referees to sent direct to the Secretary, PO Box 0, University PO, Papua New Guinea 10 September 1979. Applicants resident he UK should also send one copy to the er University Council, 90/91 Tottenham urt Road, London W1P 0DT. Further ails may be obtained from either ress. 2854(A)

UNIVERSITY OF ST ANDREWS

DEPARTMENT OF CHEMISTRY

A RESEARCH ASSISTANT with a background in Chemical Physics or Molecular Biology is required for work in the Regional Workshop of the National Foundation for Cancer Research (NFCR), located in the Chemistry Department at St Andrews.

The research project involves the investigation of the mechanism of carcinogenesis at the molecular level, and will involve both theoretical quantum chemical computations and/or experimental investigations using ESR and other spectroscopic techniques.

Applications are invited from graduates with a good Honours degree in Chemistry or Biochemistry, and preference will be given to those candidates with a strong background in quantum chemistry and an interest in molecular biology. Candidates should preferably have some experience with computer programming.

The appointment is initially for 1 year, from October 1979, at a starting salary of £3,775 per annum (under review).

Applications, with the names of two referees, should be sent as soon as possible, to the Regional Director, Dr C Thomson, Regional Workshop of the NFCR, Department of Chemistry, North Haugh, St Andrews, Fife, KY16 9ST from whom further details may be obtained.

2823(A)

DEAKIN UNIVERSITY GEELONG VICTORIA AUSTRALIA

Lecturer in Microbiology

Applications are invited from persons holding a PhD degree in Microbiology, or a closely related subject, for the post of Lecturer in Microbiology at Deakin University, Geelong, Australia.

Research interest in the microbiology of foods and/or the human environment would be particularly appropriate.

The appointment will be for an initial term of three years with review for continuing tenure after two years service.

Additional information concerning this post is available from the Association of Commonwealth Universities at the address below.

Salary: $A16,291 to $A21,401 per annum.

Applications should quote reference number 79/1/04 and include a full curriculum vitae, the names and addresses of three referees and a recent photograph and should be sent to reach the undersigned by 7 September 1979. Applicants resident in North America, Europe or Africa should send a copy of their application to the Association of Commonwealth Universities (Appointments), 36 Gordon Square, London WC1H 0PF, United Kingdom.

A. L. Pritchard, University Secretary, Deakin University, Victoria 3217, Australia. **2843(A)**

BIOGEN S.A.

a young company engaged in basic and applied research in the field of molecular biology and microbiology, and with the objective of utilizing the potential of genetic engineering for the production of substances of commercial and medical interest in such areas as health care, agriculture and energy, is inviting applications from

SENIOR AND JUNIOR SCIENTISTS

with experience in molecular biology, nucleic acid biochemistry and microbiology,

for its **Research Laboratory in Geneva,**

Switzerland.

Excellent working conditions, in close contact with leading scientists from Europe and the US.

Salary scale: Group Leaders = SFr 60-85,000, Research Associates = SFr 35-55,000.

Applicants with real interest in both basic research and its applications should send their curriculum vitae (with a description of previous experience and a list of publications) to BIOGEN Laboratory, 3 Route de Troinex, 1227 Geneva, Switzerland. W248(A)

THE QUEEN'S UNIVERSITY OF BELFAST

DEPARTMENT OF AGRICULTURAL AND FOOD CHEMISTRY

RESEARCH SCIENTIST

A challenging opportunity exists to study the mass culture o microalgae in the liquid phase o farm wastes under temperate climatic conditions. The three year project will be based or extensive laboratory and controlled environment work and will involve the establishmen and operation of a pilot plant and the evaluation of its performance with emphasis on energy balance and nutrient recovery in the alga biomass.

Candidates should have sound biological background an engineering aptitude. A PhD i bio-engineering/bio-technolog would be preferred. The startin salary is £4,233 pa + USS. Apply giving details of experience et and the names and addresses o two referees to Personnel Officer The Queen's University o Belfast, University Road, Belfas BT7 1NN, UK. Closing dat August 31, 1979. 2824(A)

UNIVERSITY OF SURREY

DEPARTMENT OF PHYSICS

Applications are invited for a Science Research Council supported

POST DOCTORAL RESEARCH FELLOW

to work with Dr R C Johnson on the theory of nuclear reactions involving heavy and light ions. Familiarity with techniques for antisymmetrization effects in nuclear collisions would be an advantage. The position is for one year.

The salary will be £6,066 per annum, on the Research and Analogous Range 1A Scale.

Applications giving the names and addresses of two referees should be sent to the Deputy Secretary (Personnel), University of Surrey, Guildford, Surrey, GU2 5XH not later than 24th August, 1979. 2803(A)

UNIVERSITY OF GLASGOW

DEPARTMENT OF DERMATOLOGY

POSTDOCTORAL RESEARCH FELLOW

Applications are invited for the post of Postdoctoral Research Fellow to work on the problem of suppressor and helper cell function in cutaneous malignancy. This post is funded by the Cancer Research Campaign. Background experience of immunological techniques is required. The appointment is for one year commencing at any time after September 1st, 1979. The salary will be commensurate with age and experience to a maximum of £6,350 (scale 1A).

Applications including a full curriculum vitae with the names of 2 referees should be made by August 27th, 1979, to Professor R M MacKie, University Dept of Dermatology, Anderson College Building, 56 Dumbarton Road, Glasgow G11 6NU. 2831(A)

NORTH NOTTINGHAM TEACHING DISTRICT

RESEARCH APPOINTMENT IN BIOMEDICAL STATISTICS

The Renal Unit at Nottingham City Hospital, in collaboration with Professor Adrian Smith, Professor of Mathematical Statistics, The University of Nottingham, wish to appoint a graduate in the mathematical or biological sciences with an interest in medical applications of statistics and computer programming.

The Post will provide varied experience in the analysis of medical data which would be relevant to a variety of potential careers. A suitable graduate would be encouraged to register for a higher degree.

Further information and application forms from the Personnel Department, Valebrook House, Sherwood Hospital, Hucknall Road, Nottingham. Tel: 625459 anytime. 2835(A)

THE MAX-PLANCK-INSTITUTE of BIOCHEMISTRY

DEPARTMENT OF STRUCTURE RESEARCH I

EXPERIMENTAL PHYSICIST

A vacancy exists for one postdoctoral research scientist. The applicant should have experience in electronics and high vacuum technology (and possibly in electron microscopy). He will be engaged in the development of methods for three-dimensional electron microscopy.

Enquiries and applications should be sent to **Professor Dr. W. Hoppe, Max-Planck-Institut für Biochemie, 8033 Martinsried/Munich, F.R.G.** W281(A)

UNIVERSITY OF SURREY

DEPARTMENT OF ELECTRONIC AND ELECTRICAL ENGINEERING

POSTDOCTORAL RESEARCH FELLOW

required for a one year appointment to work on the ion implantation of evaporated silicon thin films. Applicants should have experience of ion beam technology.

Salary according to experience will be £6,932 per annum on the Research and Analogous Staff Range 1A Scale.

Applications, consisting of a curriculum vitae and names and addresses of two referees, should be sent to Professor K G Stephens, Department of Electronic and Electrical Engineering, University of Surrey, Guildford, Surrey GU2 5XH by 24th August, 1979. 2806(A)

THE ROYAL SOCIETY

The Royal Society requires sci graduate (up to 25 years old) to assist i editorial department, mainly on mathematical & physical journals. Ger aptitude for scientific editorial v required; sound grounding in mathem essential. Progressive salary scale superannuation scheme. Commen salary up to £4,464 per annum (subje revision w.e.f. 1 October, 1979) depen on age and experience.

Applications with names, etc. of referees to the Executive Secretar Carlton House Terrace, London SV 5AG by 31 August, marking the enve 'Personal; W.G.E.'. 2865(A

ASSISTANT SCIENTIFIC SECRETARY

Cancer Research Campaign

(British Empire Cancer Campaign for Research)

Due to the growth in both the extent and scope of its scientific activities the Cancer Research Campaign, one of the largest medical charities with an annual turnover in excess of £7 million, is expanding its Scientific Department and requires an Assistant Scientific Secretary.

The Scientific Department is responsible for the administration of the Campaign's scientific (as distinct from fund-raising) endeavours and the Assistant Scientific Secretary will help the Scientific Secretary and his staff in most aspects of their work, particularly in the processing of grant applications and the subsequent administration of those that are successful: at present the Campaign is supporting over 450 projects in 80 centres. A capable and enthusiastic individual will eventually have the opportunity to undertake most facets of the administration of scientific research.

The successful candidate is likely to be aged between 28-38 with some experience of biomedical research at a postdoctoral level and with a knowledge of science and medicine in the broadest terms, as well as an interest in a career in scientific administration. The appointment will be at the level of Senior Scientific Officer with a salary scale (currently under review) of £5,678 to £7,422 (with superannuation provision), and subsequent to satisfactory completion of a two-year probationary period can be permanent.

Applications by letter, accompanied by a curriculum vitae and the names of three referees, should be sent *marked "Personal"* and not later than 14 September 1979 to:-

The Administrative Officer
Cancer Research Campaign
2 Carlton House Terrace,
London SW1Y 5AR Tel 01-930 8972

2779(A)

THE QUEEN'S UNIVERSITY OF BELFAST

POSTDOCTORAL RESEARCH ASSISTANT

DEPARTMENT OF APPLIED MATHEMATICS AND THEORETICAL PHYSICS

Required to work on the theory of the interaction of intense laser light with atomic systems (particularly multiphoton processes) with Dr S Swain. The basic requirement is a good working knowledge of quantum mechanics; experience in quantum optics would be an advantage but is not essential. The appointment supported by SRC is for three years from 1st October, 1979 or as soon as possible thereafter, with starting salary (under review) up to £4,776 with USS benefits.

Curriculum vitae and the names and addresses of two referees should be sent as soon as possible to the Personnel Officer, The Queen's University of Belfast, BT7 1NN, Northern Ireland. 2848(A)

DERBYSHIRE AREA HEALTH AUTHORITY

CENTRAL DERBYSHIRE DISTRICT

DERBY CITY HOSPITAL
Uttoxeter Road,
Derby DE3 3NE

SCIENTIFIC OFFICER

Required to extend established research programme related to immunological assessment of patients with malignant disease. Techniques involved include lymphocyte culture, sub-typing and cell freezing. Candidates should possess a degree or equivalent in biological science.

Salary scale £2,991 to £4,899 (entry point dependent on experience/qualifications).

Application forms from Sector Administrator. Ref. No. 2639.

2846(A)

KINGSTON POLYTECHNIC

SENIOR TECHNICIAN

SCHOOL OF CHEMICAL and PHYSICAL SCIENCES

Required to be responsible for a Life Science Laboratory, which is used for undergraduate teaching, research and project work and duties will include microbiology, plant studies and tissue culture work plus experimental development and investigational work.

Important post requiring someone with initiative and enthusiasm.

Salary T3/4 £4,053 to £4,953 (under review).

Details and application forms from Assistant Registrar (Personnel), Kingston Polytechnic, Penrhyn Road, Kingston upon Thames 01-549 1366. 2874(A)

UNIVERSITY OF QUEENSLAND
Australia

LECTURER IN PHYSIOLOGY

Graduates in Science, Medicine, Dentistry or Veterinary Science. Required — research experience in endocrinology, andrology, renal-cardiovascular, foetal or female reproductive physiology. 1.9.79.

Salary: $A15,786 or $A20,737 pa. Other benefits: opportunities to undertake programs of special studies, superannuation, housing assistance, travelling and removal expenses.

Additional information and application forms are obtainable from the Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF. 2815(A)

Molecular Genetics of Yeast

A Molecular Biologist/Geneticist is required to join an established group involved in the genetic modification of brewing yeasts (saccharomyces cerevisiae and saccharomyces uvarum). The person appointed will work for Britain's largest brewing group, in the research department, located at Burton on Trent, Staffordshire, which undertakes projects on behalf of the companies within Bass Limited.

The successful applicant (male/female) will contribute to the development of genetic systems for brewing yeasts, and in particular to the establishment of recombinant DNA techniques as a method for constructing organisms with specified biochemical or physiological properties. He/she will possess a Ph.D. in a relevant field of biochemistry, genetics or molecular biology, possibly with some post-doctoral experience and will already be conversant with the techniques of recombinant DNA work. The person appointed will be encouraged to maintain and extend liaison with appropriate academic laboratories, and to publish results where appropriate.

Applicants for the position should possess the ability to achieve rapid progress towards agreed objectives.

Salary will be commensurate with age and experience. The company operates a generous life assurance and pension scheme and provides comprehensive recreational facilities.

Detailed applications, including a curriculum vitae and the names of two referees should be sent as soon as possible to:-

Staff Personnel Officer,
Bass Trade Development Limited,
Burton on Trent,
Staffordshire DE14 1JZ.

Bass Limited

Trinidad

Applications are invited for the post of

RESEARCH FELLOW/ JUNIOR RESEARCH FELLOW (GEOLOGIST)

in the

SEISMIC RESEARCH UNIT

Applicants should preferably have experience in Volcanology. Salary scales 1979/80, Research Fellow TT$27,072 to 39,744 pa, Junior Research Fellow TT$21,960 to 24,072 pa (£1 sterling = TT$5.52). Family passages: FSSU; unfurnished accommodation if available at 10% or furnished at 12½% or housing allowance of 20% of pensionable salary; study and travel grant.

Detailed applications (2 copies) with curriculum vitae and naming 3 referees to be sent to the Secretary, UWI, St Augustine, Trinidad as soon as possible. Applicants resident in the UK should also send one copy to the Inter-University Council, 90/91 Tottenham Court Road, London W1P 0DT. Further details may be obtained from either address. 2838(A)

MEDICAL RESEARCH IN LEPROSY

A medical research position is available at the Armauer Hansen Research Institute (AHRI) in Addis Ababa, Ethiopia. AHRI undertakes basic research on the etiology, pathogenesis and immunology of leprosy. The Institute was founded in 1969 and is operated by the Save the Children organizations of Norway and Sweden.

The Institute is well-equipped for research within the areas of microbiology and immunology, and is located at the All Africa Leprosy Rehabilitation and Training Centre (ALERT) which makes it possible to do clinically oriented studies on patients in ALERT's hospital. The Institute staff consists of three senior researchers (of whom one is the Institute Director), two research fellows, two laboratory engineers, two laboratory technicians, four laboratory assistants, an administrator, two secretaries and other personnel — altogether 24 people.

Applicants should have a background in microbiological and/or immunological research, preferably a medical degree, although this is not an absolute requirement. The normal contract period is at least two years.

Further information concerning this position can be obtained from Professor Morten Harboe, Institute for Experimental Medical Research, Ullevål Hospital, Oslo 1, Norway. Telephone 2/60 03 90.

Applications accompanied by a curriculum vitae, a list of publications and personal references should be sent within three weeks after the appearance of this announcement to REDD BARNA (Norwegian Save the Children), Lilletorget 1, Oslo 1, Norway. W280(A)

(Dr. G. J. Hämmerling)

Postdoctoral and staff positions available.

Research topics: T cell receptors, T-hybridomas, H-2 complex, V-gene expression in T and B cells, monoclonal antibodies against cell surface and V-region determinants, idiotypic interactions in the immune system.

Salary about 25,000-30,000 DM pa according to BAT scale.

For further details please contact German Cancer Research Center, Administration, Im Neuenheimer Feld 280, 6900 Heidelberg.

W284(A)

ROYAL POSTGRADUATE MEDICAL SCHOOL

DEPARTMENT OF IMMUNOLOGY

RESEARCH/SENIOR RESEARCH OFFICER

Required for the remaining 2 years of an MRC funded project concerned with a clinical and experimental study of immunological function and graft versus host disease following bone marrow transplations, undertaken jointly between the Immunology and Haematology Departments at the Royal Postgraduate Medical School, Hammersmith Hospital. The post becomes vacant October 1st 1979, but an overlap of 2-4 weeks with the present holder is desirable and could be arranged.

Starting salary up to £5,777 a year. Applicants should have experience and preferably a higher degree in cellular immunology,and be familiar with tissue culture techniques.

Application forms and further particulars may be obtained from the Royal Postgradualte Medical School, Personnel Office, 150 Du Cane Road, London W12 0HS quoting ref no 21/200/N.

Closing date: 10th September 1979. 2873(A)

LEICESTER POLYTECHNIC

SCHOOL OF CHEMISTRY

SENIOR TECHNICIAN IN MASS SPECTROMETRY

Applications are invited from graduates in a relevant science for this post which will involve operating a new mass spectrometer system comprising a PYE 204 Chromatograph, a VG 16 F Mass Spectrometer and a VG Display Digispec Data System.

In addition to providing a service for the teaching and postgraduate work of the Science Faculty there will be novel and interesting duties in connection with the provision of a service to industrial users on a commercial basis; this will involve extensive liaison with industrial laboratories.

Applicants should have at least three years experience as mass spectroscopists and preferably be competent in the maintenance of the system. Salary £4,461 to £4,761 plus £312 supplement pa.

Application forms available from Staffing Officer, Leicester Polytechnic, PO Box 143, Leicester LE1 9BH. Tel (0533) 551551 ext 2303. 2818(A)

UNIVERSITY OF EAST ANGLIA

Norwich

LECTURER IN CHEMICAL PHYSICS

in the School of Chemical Sciences, tenable from October 1979, for a period — probably 4 years — during which Professor N Sheppard, FRS, is in receipt of an SRC Senior Fellowship. Preference will be given to candidates with experience in the field of photochemistry or reaction kinetics. Salary will initially be within the range £4,333 to £6,066 on the scale £4,333 to £8,992 (under review) plus FSSU/USS benefits.

Applications (one copy only) which should contain a full curriculum vitae including exact date of birth, together with the names and addresses of three persons to whom reference may be made, should be lodged with the Establishment Officer, University of East Anglia, Norwich NR4 7TJ, from whom further particulars may be obtained (telephone 0603 56161 ext 2126) by not later than 31 August 1979. No forms of application are issued. In naming three referees you are requested to give only the names of those who can immediately be approached by the University. 2810(A)

UNIVERSITY OF BRISTOL

School of Chemistry

POSTDOCTORAL RESEARCH ASSISTANT

Applications are invited for the post of Research Assistant to continue studies on the identification of reaction products from the ozonisation of organic compounds in potable waters. Instrumentation includes HPLC, capillary GLC and computerised GC-MS. Technical assistance is available. The project is financed by the Water Research Centre and relates to the purification of drinking water by ozone.

The appointment is for one year, with the possibility of renewal for a second year. Starting salary within the range £4,232 to £5,048 per annum. (Scale subject to revision with effect from 1st October, 1979).

Please send applications, by 20th August, with details and the names and addresses of two referees, to Dr J R Maxwell, Organic Geochemistry Unit, School of Chemistry, University of Bristol, Bristol BS8 1TS. 2749(A)

UNIVERSITY COLLEGE OF NORTH WALES

Bangor

DEPARTMENT OF MARINE BIOLOGY

RESEARCH ASSISTANTS

Applications are invited for two posts in the College's Marine Science Laboratories, one in the field of Microbiology and the other in Marine Chemistry/Phytoplankton studies.

The successful applicants will have first degrees in appropriate subjects, and will be required to participate in a research project which will include work at sea.

The appointments will be until 30th June 1980 in the first instance, and will be to the Research and Analogous IB scale. Starting salary will be within the range — £3,689 to £4,232 per annum.

Applications (two copies), giving details of qualifications and experience, together with the names and addresses of two referees, should be sent to the Assistant Registrar (Personnel), University College of North Wales, Bangor, Gwynedd LL57 2DG, by not later than 20th August, 1979. 2804(A)

UNIVERSITY OF MANCHESTER

DEPARTMENT OF BIOCHEMISTRY

POSTDOCTORAL RESEARCH ASSOCIATE AND POSTGRADUATE RESEARCH ASSISTANT

Applications are invited for these posts, which are associated with a project, directed by Professor C.I. Pogson, concerning the regulation of tryptophan hydroxylase activity in brain. Postdoctoral applicants should hold (or anticipate) a PhD in Biochemistry, Neurochemistry or a related discipline; some enzymological experience will be an advantage.

Candidates for the Research Assistantship should have a first degree in Biochemistry. Both posts are tenable for three years from October 1st.

Initial salary ranges: Research Associate, £4,333 p.a. to £4,910 p.a. Research Assistant £3,775 p.a. to £4,333 p.a. Superannuation.

Further particulars and application forms (returnable by August 31st) from the Registrar, University of Manchester, M13 9PL. Quote ref: 186/79/N. 2857(A)

UNIVERSITY COLLEGE OF NORTH WALES

Bangor

DEMONSTRATOR AGRICULTURE

Applications are invited for the above post in the College's Department of Agriculture, with particular responsibilities in Grassland Production. The person appointed will assist in the teaching of undergraduates and will be expected to participate in research on the efficiency of utilisation of grassland, for which it may be possible to register for a higher degree.

Applicants should have recently graduated in Agriculture or a related discipline. Some postgraduate experience in grassland agronomy would be an advantage although not essential.

The appointment, to commence on 1st October 1979, will be within the range: £3,689 to £4,232 per annum, and will be for one year in the first instance, with the possibility of renewal subsequently.

Applications (two copies), giving details of qualifications and experience, together with the names and addresses of three referees, should be sent to the Assistant Registrar (Personnel), University College of North Wales, Bangor, Gwynedd LL57 2DG, from whom further particulars may be obtained. Closing date 20th August, 1979. 2805(A)

JAMES COOK UNIVERSITY OF NORTH QUEENSLAND

SCHOOL OF BIOLOGICAL SCIENCES

Applications are invited from suitably qualified candidates for enrolment in research doctorate and master degrees within the School of Biological Sciences. The School which is made up of the Departments of Botany, Marine Biology and Zoology is ideally situated for tropical studies. Research currently being carried out includes:

Botany: Plant physiology, taxonomy and ecology, systematics, ecology and physiology of marine and freshwater algae, taxonomy and ecology of fungi.

Marine Biology: Coral reef, estuary, mangrove and inshore ecology, community structure and trophodynamics of plankton and benthos, functional morphology, behaviour and sensory physiology of marine invertebrates, bioaccumulation of metals and pollution.

Zoology: Fisheries and marine mammal biology, estuarine and intertidal ecology, sensory and physiology, invertebrate larval studies, taxonomy of marine animals.

Further details and application forms may be obtained from the Registrar, James Cook University of North Queensland, Post Office, James Cook University, Queensland 4811, Australia. 2816(A)

COLAISTE NA HOLLSCOILE CORCAIGH
UNIVERSITY COLLEGE CORK
RESEARCH ASSISTANT

A Research Assistant is required for 1 October 1979 with postgraduate experience in enzyme purification and characterisation to work on oxygen and hydrogen peroxide metabolism in lactic acid bacteria.

Candidates should preferably have a PhD in microbiology/biochemistry. The appointment is funded by the National Board for Science and Technology of Ireland. Starting salary is £3,837 for a post-doctoral worker (salary under review). The post is renewable for a second year.

Curriculum vitae with names of two referees should be sent to:
Dr S. Condon, Department of Microbiology, University College, Cork, (Ireland).
Closing date for receipt of applications: Friday, 31st August 1979. 2802(A)

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL
(University of London)

VACANCIES
RESEARCH FELLOWS

Post-doctoral research positions are available in the Department of Structural Biology. Applicants should be familiar with the techniques used in one or more of the following areas: Mammalian physiology; Electron Microscopy; Histochemistry.

Appointments will be for three years commencing as soon as possible. Details from the Establishment Officer, St. George's Hospital Medical School, Cranmer Terrace, London SW17 0RE. 2840(A)

POSTDOCTORAL POSITIONS IN ADRENERGIC RECEPTOR RESEARCH

Two positions available in September 1, 1979. The first position will involve an investigation into the relationship between PMN ß-receptor concentrations, glucocorticoids and asthma. The second position will involve the large scale purification of cardiac ß-adrenergic receptors.

Applicants should send curriculum vitae and names of three references to:
Dr J. Craig Venter, Department of Pharmacology and Therapeutics, School of Medicine, State University of New York at Buffalo, 127 Farber Hall, Buffalo, NY 14214. An Equal Opportunity/Affirmative Action Employer. W282(A)

DIRECTOR OF RESEARCH COMPUTER FACILITY AND ASSISTANT PROFESSOR OF BIOLOGICAL CHEMISTRY

Responsibility for operation and further development of Research Computer Facility serving multiple users; opportunity to develop new programs; graduate level teaching and research; PhD with relevant experience required. Position available November 1, 1979.

Applications and curriculum vitae are to be sent to Dr Eugene A Davidson, Dept of Biological Chemistry, Box C, The Milton S Hershey Medical Center, The Pennsylvania State University, Hershey, PA 17033 USA. Applications will be received until October 31, 1979. An Equal Opportunity/Affirmative Action Employer. W278(A)

RESEARCH CENTRE
located in
NANCY — France
seeks
PATHOLOGIST

to take charge of the haematology and histopathology laboratories in its Industrial Toxicology Department.

Applicants should have a sound knowledge of anatomy and histology and five years' experience in the field. Duties include: study of sections; taking part in general toxicology and industrial cancer research; leading a team of seven people.

Fluent knowledge of French required.

Gross annual starting salary between 108,000 Frs. and 125,000 Frs.

Candidates should send C.V. with photograph and list of works and publications to Mr Saugier, Personnel Manager, INRS, 30 rue Olivier-Noyer, F—75680 Paris, Cedex 14, France. W285(A)

KING'S COLLEGE LONDON
DEPARTMENT OF PHYSICS

LABORATORY TECHNICIAN GRADE 5

Responsibilities include developing, constructing and modifying apparatus for teaching requirements and student projects etc, maintenance, servicing and repairing of equipment and the preparation of graphs, blueprints and engineering drawings. The post also involves the training of juniors and some supervision of other technical staff. Applicants should be suitably qualified and have 7-9 years relevant experience. Salary on scale £3,998 to £4,580 pa inclusive (under review). Five weeks annual holiday. Contributory pension scheme. Interest-free loans for annual rail season tickets.

Apply in writing with full details to The Head Clerk (Ref: 217831/N), King's College London, Strand, WC2R 2LS. 2814(A)

UNIVERSITY OF LIVERPOOL
DEPARTMENT OF BIOCHEMISTRY

Applications are invited for the post of Postdoctoral Senior Research Assistant in the Department of Biochemistry. The post is supported by the SRC for two years from 1st October 1979, at an initial salary of either £4,232 or £4,505 per annum.

The field of study is 'The control of chromatic adaptation in Cyanobacteria'. Applications are invited from biochemists and microbiologists. Experience on the isolation and biochemistry of RNA an advantage.

Applications, together with the names of three referees, should be received not later than 24th August, 1979, by The Registrar, The University, PO Box 147, Liverpool L69 3BX, from whom further particulars may be obtained. Quote ref RV/733/N. 2829(A)

TECHNICIAN/ RESEARCH OFFICER
required by our
VIRAL ONCOLOGY

laboratory to work in close collaboration with a member of the scientific staff on research into the genetics of avian and murine oncogenic viruses. HNC/degree. Experience in tissue culture, virological and biochemical techniques an advantage, but training in specific procedures will be given. Salary range £3,615 to £5,256. For further information and application form write or telephone Miss S M Hurley, Imperial Cancer Research Fund, Lincoln's Inn Fields, WC2 on 242 0200 ext 305, quoting reference 340/79. 2847(A)

ROYAL FREE HOSPITAL SCHOOL OF MEDICINE AND ST MARY'S HOSPITAL MEDICAL SCHOOL

Applications are invited for a postdoctoral Research Assistant to work on experimental neuropathies employing freeze-fracture techniques. The post will be held jointly between the Department of Neurological Science at the Royal Free Hospital, Hampstead, and the Department of Anatomy, St. Mary's Hospital Medical School.

Applicants, who should have previous experience in electron microscopy, are requested to send a curriculum vitae and the names of two referees by 24 August, 1979 to Professor P.K. Thomas, Royal Free Hospital, Pond Street, London, NW3 2QC, from whom further particulars may be obtained. 2851(A)

KING'S COLLEGE LONDON

TEACHING TECHNICIAN GRADE 2B

Required to run the teaching laboratories of the Biophysics Department. An interesting post concerned with a wide range of courses. Other duties include helping with the animal unit and assisting academic staff with research.

Minimum qualification ONC or equivalent. Salary on scale £3,281 p.a. rising to £3,662 p.a. inclusive (under review). 5 weeks annual holiday. Contributory pension scheme. Interest-free loans for annual rail season tickets. Day release available for further relevant qualifications.

Apply in writing with full details to: The Head Clerk (Ref: 217832), King's College London, Strand, WC2R 2LS. 2859(A)

UNIVERSITY OF LIVERPOOL
DEPARTMENT OF PHARMACOLOGY AND THERAPEUTICS

CHEMIST/BIOCHEMIST

Applications are invited for the post of Senior Research Assistant, supported by the Wellcome Trust, for studies on the relationship between the metabolism and toxicology of synthetic steroids. Initial salary will be £4,232 pa and the project is financed for three years.

Applications, together with the names of three referees should be received not later than 21st August, 1979, by The Registrar, The University, PO Box 147, Liverpool L69 3BX, from whom further particulars may be obtained. Quote ref RV/730/N. 2828(A)

MAX-PLANCK-INSTITUT FÜR GENETIK
Berlin-Dahlem

A position is available for a

POSTDOCTORAL FELLOW

to work on the interactions between ribosomal proteins or between ribosomal RNA and proteins. This work will involve both biochemical and biophysical techniques. The position will be funded by the DFG until the end of 1981 at a salary of approximately 40,000 DM/year (BAT IIa).

Applications, including a C.V. and the names of at least two persons from whom references can be obtained, should be sent to Dr Jan Dijk, Max-Planck-Institut für Molekular Genetik, Abt. Wittmann, Ihnestrasse 63-73, D-1000 Berlin 33, West Germany. W283(A)

LIVERPOOL SCHOOL OF TROPICAL MEDICINE

TECHNICIAN (grade 4)

required for research project in the Department of Tropical Paediatrics. Applicants should possess HNC or equivalent qualification and have experience of alectrophoretic spectrophotometric and immunometric (ELISA) techniques. The appointment will be for 3 years.

Applications in writing to The Department of Tropical Paediatrics School of Tropical Medicine, Pembroke Place, Liverpool L3 5QA, by 31st August 1979. 2867(A)

UNIVERSITY OF KEELE
DEPARTMENT OF BIOLOGICAL SCIENCES

DEMONSTRATOR

Applications invited for post of Demonstrator initially for one year; salary £3,775 per annum, together with membership of University Superannuation Scheme. Candidates should have a good degree in a biological science with some research, and ideally teaching experience. Candidates with interests in parasitology given preference, but other areas not excluded.

Further particulars and application forms from the Registrar, The University, Keele, Staffs, ST5 5BG to whom completed forms should be returned before 31st August, 1979. 2812(A)

UNIVERSITY OF BRISTOL
DEPARTMENT OF PHYSIOLOGY

TECHNICIAN GRADE 4

required for a research laboratory concerned with mammalian neurophysiology. Applicants should be over 21 and have an ONC or equivalent qualification. They should have experience in either electronics or general laboratory work. The salary will be in the range of £2,955 to £3,402 per annum (scale under review).

Applications consisting of a brief curriculum vitae and the names of two referees should be sent to Dr Sheila Carter, Department of Physiology, The Medical School, University Walk, Bristol BS8 1TD as soon as possible. 2833(A)

QUEEN ELIZABETH MEDICAL CENTRE
Central Birmingham Health District
Edgbaston, Birmingham 15

BASIC GRADE BIO-CHEMIST

Applicants are invited for a new post in the Clinical Chemistry Department of a large teaching hospital. It will offer wide routine experience in a department recognised for training for MCB/MRC Path, and opportunities for development and research work. The Queen Elizabeth Medical Centre is pleasantly situated three miles from Birmingham City Centre and has excellent staff facilities. Temporary accommodation may be available.

Details of the post and application forms are available from the Sector Personnel Officer, Queen Elizabeth Hospital, Birmingham B15 2TH or telephone 021 472 1311 ext 165. Candidates may visit the department by arrangement with Dr A M Bold, on extension 139. Interviews will be held during the second week in September. 2817(A)

ASSISTANT PROFESSOR

Applications are invited for the position of assistant professor in the Department of Microbiology at the University of British Columbia. Of special interest are persons able to establish a research program in yeast or fungal molecular genetics. The position is available immediately. Please send full curriculum vitae and the names of three referees to Dr J J R Campbell, Professor and Head, Department of Microbiology, University of British Columbia, Vancouver BC V6T 1W5. W276(A)

FELLOWSHIPS

THE UNIVERSITY OF WESTERN AUSTRALIA
Perth

UNIVERSITY RESEARCH FELLOWSHIPS (POST-DOCTORAL)

Not less than two Research Fellowships will be offered, to be taken up in 1980. Appointment will be for one year in the first instance with the possibility of renewal for a second year; Fellowships could possibly be renewed also for a third year, but in competition with any new applications. The Fellowships will be enable in the following academic departments for work in the broad areas stated below:

Anatomy and Human Biology: Analysis of synapses in the central nervous system with emphasis on their functional state.

Biochemistry: Hormonal control of cytochrome synthesis in mitochondria of developing rat ovary.

Botany: DNA repeated sequences in native plant groups.

Physical and Inorganic Chemistry: Dynamic stereochemistry.

The Fellowships are intended primarily for PhD graduates (normally from other universities), or those with equivalent qualifications, who by publication and in other ways have demonstrated significant research capability. Salary will be within the range $A14,041 to $A16,085 pa and appointees may in certain circumstances be considered for admission to a superannuation scheme. Fellows may be given the opportunity to participate in teaching.

Applications in duplicate setting out full personal particulars, qualifications and experience, and the proposal for research during the tenure of the Fellowship should reach the Acting Staffing Officer, University of Western Australia, Nedlands 009 Western Australia by 24th September, 1979. Candidates should request three referees to write immediately to the Acting Staffing Officer. 2869(E)

RESEARCH FELLOWSHIP
Imperial Cancer Research Fund
Mill Hill Laboratories
London NW7 1AD

A post-doctoral Fellow is sought to join a group working on the control of differentiation of stalk and spore cells in Dictyostelium discoideum. The Fellow would be expected to employ genetical and biochemical techniques to analyse the cell interactions involved in differentiation in this organism.

Appointment will be for three years. Salary with entry according to qualifications and experience within range £5,823 to £7,129.

Further information from Dr J Gross (01 959 3236). Application with curriculum vitae and names of two referees, should be sent to The Secretary, Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2A 3PX, by 30th September, 1979, quoting reference 345/79. 2862(E)

UNIVERSITY OF SURREY
DEPARTMENT OF MICROBIOLOGY
POST-DOCTORAL RESEARCH FELLOWSHIP

A post-doctoral research fellow is required for a three year MRC-supported project to determine the DNA sequence of the penicillinase (B-lactamase) gene of the resistance plasmid R46. This is part of a programme of research into the structure and function of this unusual penicillinase and its relationship to other B-lactomases.

Experience in DNA sequencing is not essential, but applicants should have some experience in plasmid biology or recombinant DNA technology. The starting date will be October 1st, 1979 or as soon as possible thereafter. The commencing salary will be £4,333 per annum on Research and Analogous Range 1A.

Applications, including curriculum vitae and naming two referees, should be sent as soon as possible to Dr J W Dale, Department of Microbiology, University of Surrey, Guildford, Surrey GU25 5XH, from whom further information may be obtained. Closing date 24th August, 1979. 2808(E)

UNIVERSITY OF SOUTHAMPTON
DEPARTMENT OF MICROBIOLOGY
RESEARCH FELLOWSHIP

Applications are invited for the above post in an established research group concerned with molecular mechanisms in infectious diseases. The post, which is funded by the MRC until March 1984, is suitable for candidates who already hold or who expect to be awarded a PhD in the areas of cell-biology or membrane bio-chemistry. Candidates with experience in other fields will be considered. The successful applicant will be concerned with the isolation of and characterisation of those gonococcal surface components involved in the interaction with host cell receptors. Starting salary at an appropriate point on the 1A scale according to age, qualifications and experience (£4,333 to £6,066).

Informal enquiries regarding the post will be welcome and may be made through Professor P J Watt, Tel 0703 777222 ext. 3893. Applications with curriculum vitae and names of two referees to Microbiology Department, South Laboratory and Pathology Block, Southampton General Hospital, Southampton SO9 4XY. 2872(E)

MRC
Medical Research Council

Travelling Fellowships 1980-81

The Council invites applications for travelling fellowships, available for the academic year 1980-81, from suitably qualified candidates with research experience. Clinical applicants should be of at least NHS Registrar status while non-medical graduates are expected to hold a PhD/DPhil degree. The majority of these fellowships may be held in any country abroad although certain of the awards are restricted to the USA or France.

The closing date for applications is *30 Septmeber 1979.* **Application forms and further information may be obtained from Training Awards Group, Medical Research Council, 20 Park Crescent, London W1N 4AL, Telephone 01-636 5422 (Extension 240).** 2821(E)

EMBO

European Molecular Biology Organization

LONG TERM FELLOWSHIPS IN MOLECULAR BIOLOGY AUTUMN 1979 AWARDS

Next deadline: August 31, 1979

EMBO long term fellowships are initially awarded for one year. Applications for a renewal for a second year and subsequently **in cases of exceptional scientific merit for a third year** are considered.

To be eligible a candidate must hold a doctors degree. Preference will be given to European and Israeli applicants wishing to work within Europe or Israel. EMBO long term fellowships are not, however, awarded for exchanges between laboratories within any one country. Applications for fellowships to be held outside Europe and Israel are considered but they have a lower priority, as do applications from non-European scientists wishing to work in Europe or Israel.

Successful applicants will be notified of their awards on October 29, 1979.

Further details and application forms may be obtained from Dr J. Tooze, Executive Secretary, European Molecular Biology Organization, 69 Heidelberg 1, Postfach 1022.40, F. R. Germany. W275(E)

UNIVERSITY OF BIRMINGHAM
DEPARTMENT OF BIOCHEMISTRY
RESEARCH FELLOWSHIP

A Research Fellow is required from 1st October 1979 until 31st October 1980 for work supported by the Medical Research Council on hepatic glucokinase. The Fellow will work with Professor D G Walker and continue a project concerned with several aspects of the metabolic regulation of the enzyme.

Salary on scale starting at £4,333 (October scales) according to age and experience, plus USS: maximum starting salary £6,066.

Applications by 31st August, 1979 to Miss L R Heyes, Senate Registry, University of Birmingham, PO Box 36, Birmingham B15 2TT, from whom further particulars may be obtained. 2849(E)

UNIVERSITY OF KEELE
DEPARTMENT OF PHYSICS
RESEARCH FELLOWSHIP
Synchrotron Radiation Protein Crystallography

Applications are invited for a three year SRC supported Post Doctoral Fellowship commencing on 1st October or as soon as possible thereafter to work with Dr J. R. Helliwell on the X-ray crystallographic study of 6-phosphogluconate dehydrogenase from Bacillus stearothermophilus utilising the Synchrotron Radiation Source presently under construction at Daresbury Laboratory as well as facilities within the Department. Salary starts at point 3 of the research scale 1A £4,910 to £5,488. Experience in the field advantageous but not essential.

Further particulars and application forms from The Registrar, The University, Keele, Staffs, ST5 5BG to whom completed forms, as well as curriculum vitae and details of research experience, should be returned as soon as possible. 2850(E)

THE UNIVERSITY OF LEEDS
FACULTY OF MEDICINE
THE EMMA AND LESLIE REID FELLOWSHIP

Applications are invited for the above Fellowship tenable in the University for a fixed period of up to three years for a person qualified to prosecute research in connection with diseases of the heart or brain (or kindred diseases). A medical qualification is not essential.

Remuneration will be at an appropriate point on either the University clinical scale (£4,296 to £8,281 under review from 1 April 1979) or non-clinical Research and Analogous scale (£4,333 to £7,521 under review from 1 October 1979).

Application forms and further particulars may be obtained from the Registrar, The University, Leeds LS2 9JT, quoting reference number 93/3/D. Closing date for applications 12 October 1979. 2875(E)

UNIVERSITY OF BIRMINGHAM
DEPARTMENT OF GENETICS
RESEARCH FELLOWSHIP

Applications are invited for a post-doctoral research fellowship funded by an SRC grant to Dr D A Smith. The project is the analysis of spore germination in *Bacillus subtilis* using germination mutants, conventional genetic analysis and gene manipulation procedures.

The post is tenable for three years. Salary will be on the RF1A scale £4,333 to £7,521 (as from October 1st, 1979), plus superannuation. Maximum starting salary will be £4,910.

Further particulars are available from the Assistant Registrar, Science and Engineering, University of Birmingham, PO Box 363, Birmingham, B15 2TT to whom applications (three copies) including full curriculum vitae and naming three referees, should be sent by Friday 24th August, 1979. Please quote ref: NL8. 2819(E)

ROYAL FREE HOSPITAL SCHOOL OF MEDICINE
(University of London)
RESEARCH FELLOWSHIP

in field of microdosimetry of ionizing radiations, using a new 700kV ion accelerator, tenable for 3 years in Academic Dept of Medical Physics, Pond St, London NW3. Opportunities for student teaching. On scale £3,717 to £5,332 plus £502 London Allowance.

Applications with c.v. and two referees to the School Secretary, RFHSM, 8 Hunter St, London WC1N 1BP by 31st August, 1979. 2811(E)

AWARDS

INVITATIONS TO NOMINATIONS FOR THE KUWAIT FOUNDATION FOR THE ADVANCEMENT OF SCIENCES
ANNUAL PRIZES

The KFAS prizes were institutionalised to recognise distinguished accomplishments in the arts, humanities and sciences.

KFAS prizes are awarded annually in the following categories:

A Basic Sciences
B Applied Sciences
C Arabic and Islamic culture
D Arts and Letters
E Social and economics sciences

The prizes for 1979 will be awarded in the following fields:

A Chemistry
B Energy
C History of Arabic medicine
D Contemporary dramatic movement in the Arab world
E The rôle of petroleum in development.

Background

I Nominations to these prizes are accepted from academic and scientific centres, learned societies, past recipients of the prizes and peers of the nominees. No nominations are accepted from political entities.

II The selection of the special topics for each prize and of the prize winners are recommended to KFAS board of directors by the KFAS prize council, an autonomous body of distinguished scientists.

III Two prizes are awarded in each category, a prize to recognise the output of a distinguished arab, and prize to recognise the output of a distinguished Kuwaiti.

IV Each prize consists of a cash sum of KD5,000 (Dollars 18,000), a gold medal and a certificate of recognition.

Nominations, including a complete curriculum vitae and an updated list of publications of the candidate should be addressed before September 15, 1979 to:

The Prize Council
Kuwait Foundation for the Advancement of Sciences
PO Box 25263 Safat
Kuwait W279(N)

ASSISTANTSHIPS

THE UNIVERSITYOF SHEFFIELD
DEPARTMENT OF METALLURGY
POST-DOCTORAL RESEARCH ASSISTANTSHIP (SRC)

Applications invited from men and women scientists and engineers for a vacancy in a interdisciplinary team working on evaporation and fuming of metals. Experience of lase applications desirable but not essential. Tenable to 30 June 1981. Salary up to £4,776 a yea (under review) with superannuation.

Write to Dr E R Buckle, Department of Metallurgy, the University, Sheffield S1 3JD Quote ref: R317/G. 2845(P)

UNIVERSITY OF DURHAM
DEPARTMENT OF PHYSICS

Applications are invited for an SRC funded

POSTDOCTORAL SENIOR RESEARCH ASSISTANTSHIP

tenable for 2 years from 1st October, 1979 to work in the field of Gamma Ray Astronomy with Professor A W Wolfendale FRS, and Dr A W Strong.

The work involves analysis of gamma ray data accumulated by satellite borne detectors and has as a major objective a study of the distribution of cosmic ray particles in the Galaxy (and beyond) whose interactions with the interstellar gas generate some of the quanta. Preference will be given to applicants with Research experience in Galactic structure, the interstellar medium or related fields. Computer experience would also be an advantage.

Initial salary in the range £4,333 to £4,910 on Range 1A plus superannuation.

Applications (3 copies) naming three referees should be sent by 31st August 1979 to the Registrar and Secretary, Science Laboratories, South Road, Durham DH1 3LE from whom further particulars may be obtained. 2754(P)

COURSES

EUROPEAN MOLECULAR BIOLOGY ORGANISATION

Course on:
TERATOMAS
University of Glasgow, 17-29 March 1980
Organisers: M L Hooper (Glasgow) C F Graham (Oxford)

Lectures and practical work will cover the following main topics:

Production and properties of mouse teratomas *in vivo*, differentiation of teratomas *in vitro*, embryology and genetics of the mouse, embryo culture, blastocyst injection, somatic cell genetics, cell surface, polyacrylamide gel techniques, histology, immunological techniques, erythroid differentiation. Guest lecturers will include L C Stevens (Bar Harbor), G R Martin (San Francisco), M J Evans (Cambridge), B L M Hogan (London), S Povey (London), P Goodfellow (Oxford), M Osborn (Göttingen).

Participation is open to postdoctoral and final year predoctoral workers from EMBO countries. Course fee £50 including bed and breakfast accommodation. Number of places limited to 20. A small number of EMBO fellowships will be available for applicants who could not otherwise attend.

Further details and application forms from Dr M L Hooper, Institute of Genetics, Church Street, Glasgow G11 5JS, Scotland. *Closing date for applictions: 30 November, 1979.* 2830(D)

CONFERENCES

SCIENTIFIC SYMPOSIA LTD

Scientific Symposia would like to announce the forthcoming conference.

PHOTOGRAPHY IN PRACTICE

Getting successful results from photographic and video techniques in science and technology.

To be held on 3rd & 4th October, 1979 at the Sudbury Conference Centre, London EC1.

Papers will include:

Keynote lecture: The use of photographic and video techniques to capture and communicate information.
Professor H. A. F. Dudley, Academic Surgical Unit, St Mary's Hospital, London.

Techniques of photomacrography: *Dr. Brian Bracegirdle*, Keeper of the Wellcome Museum, The Science Museum, London.

Basic cine photography: *Dr. P. N. Cardew*, Department of Audio Visual Communication, St. Mary's Hospital Medical School, London.

A practical guide to systems for video recording: *Adrian Hope*, Audio/Video/Patents Consultant, "New Scientist", London.

Review Lecture. Visual psychology in relation to imaging, *Professor F. W. Campbell*, Physiological Laboratory, Cambridge.

How necessary is a high quality image as opposed to simply capturing the information? *George H. Lunn*, Atomic Weapons Research Establishment, Aldermaston, Berks.

Basic time-lapse and high-speed photographic techniques and problems. *John Rendel*, Gordon Audiovisual Ltd., London and *George H. Lunn*, Atomic Weapons Research Establishment, Aldermaston, Berks.

A practical demonstration of audio-visual presentation. *Dr P N Cardew*, Department of Audio Visual Communication, St. Mary's Medical School, London.

Review Lecture: Holography as a viable visual medium. *N. J. Phillips*, Department of Physics, University of Technology, Loughborough, Leicestershire.

To: Beverly Humphrey, Scientific Symposia Ltd., 33/35 Bowling Green Lane, London EC1R 0DA.

Please send me further details on the conference PHOTOGRAPHY IN PRACTICE

If you've been wishing you could get rid of the inconvenience and difficulties of iodinating proteins, here is an easy way to do it. Get our simple, reliable Radioiodination System [^{125}I] – everything you need, ready for your protein.

We've selected a mild reaction method (enzymatic lactoperoxidase) to preserve your protein specificity. We've made sure that there are no contaminants to interfere with proper iodination. And we've tested each lot in a complete iodination procedure.

The ingredients are: Sodium iodide [^{125}I], iodination reagent, sterile protein-free buffer, 1% β-D glucose to activate the system, and a volatile radioiodine trap.

This system is the new way to make iodination straightforward and reliable. Send for the protocol to start saving time and trouble.

Not for use in humans or clinical diagnosis.

Adaptability is getting more important.

For stereomicroscopes, too.

I don't have to explain to students the textile weaves which they see on the **closed-circuit TV** monitor.

I don't study the behaviour of small organisms in **dark field**, and as for the inspection of integrated circuits in **coaxial incident light** – well, I just wouldn't know what to look for. But, if I wanted to, I could use my Wild stereomicroscope and its accessories for all of these things.

Minerals are my line. With my Wild instrument I can see crystal structures **in three dimensions;** with the MPS Microphoto System I can **photograph them in sharp detail.** I've measured inclusions with the measuring eyepiece and sketched them with the drawing tube: with precision and clarity. Now I want to buy a **rotating polarising stage** for studying my small collection of thin sections. I really thank my lucky stars that I chose a Wild stereomicroscope; it would have been disastrous to have been unable to add all of these accessories. Have a look at them – most can be used on any Wild stereomicroscope, and they are shown in brochure M1 180e.

Science in the Third World: What's to be done?

The British family Wilj announce two talented new members

Gamma Counter 2001-S

* 50mm Crystal, 50mm shielding
* Multiple-channel facilities (SMIC)
* Additional user variable window
* Digital display directly in KeV
* Accepts alternative external counting heads
* Incorporates our unique easy to calibrate system

RIA Data-Processor 2701

* Easy to use — it asks you the questions
* Dual-channel
* Choice of curve fits: Polylinear, Logit/log & Spline
* Statistical checks

These two new additions increase Wilj's long lead on other lower-cost RIA equipment. This combination can count and process **double-isotope kits** in one simple operation.
Higher energy isotopes can be counted with the larger crystal and increased shielding.

Data-processing is no problem with Wilj peripheral options. Teletypes, paper tape, data-logger and the Hewlett-Packard 9815A programmable calculator and software can all be accommodated.

Whichever combination you choose, all Wilj products come complete with an unconditional 2 year guarantee. (U.K. Only)

LEADING UK MANUFACTURERS OF

The SCORAH Automatic Electric all glass WATER STILL (patented)

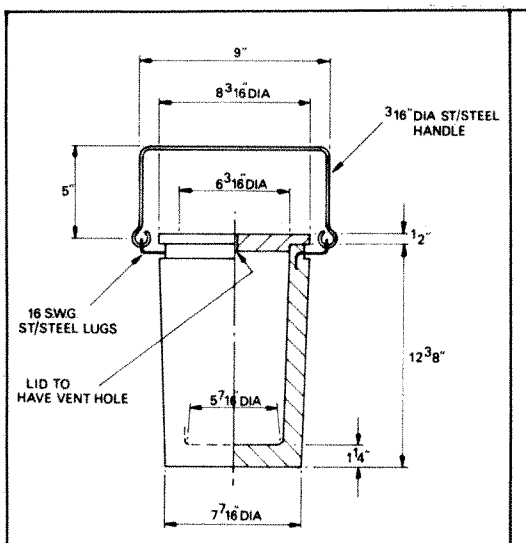
Automatic Can be left on without attention. Heater current cuts off if water supply is interrupted, or inadequate or forgotten. When receiver (5 litres capacity) is full, current cuts off. When distilled water is drawn from receiver, the still resumes operation until receiver is refilled.

Purity Electrostatically charged condenser droplets can pick up fumes, dust and air-borne organisms from the laboratory atmosphere. The design of the receiver vessel ensures absence of such contamination.

Efficiency Heater of Scorah design and manufacture, consumption 1,700 watts, output 2.4 litres per hour (the full theoretical yield). Cost less than 2p per gallon at ½p per unit.

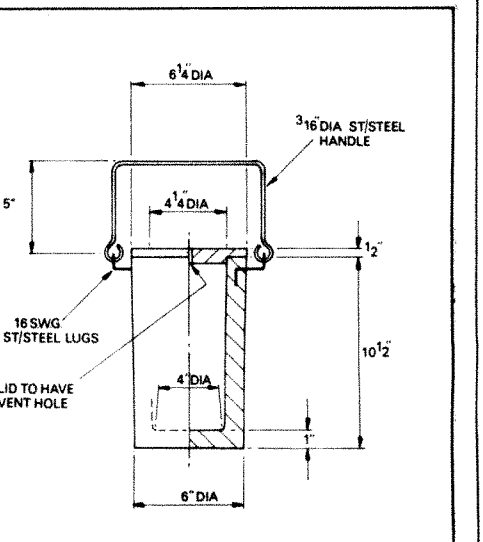
Safety The heating element is out of contact with the feed water, thus eliminating danger from "live" water supply or electrolytic effects of "burn out".

Assembly No retort stands of clamps are required. The 2½-in. diameter ball joint gives a stainless set-up. Outlet cap on boiler for quick periodical drain-off of sediment. The still may be installed on a shelf or platform about 1 ft. above bench level near a sink and enclosed in a transparent plastic cover to keep out dust.



Heat-resisting glass. Interchangeable ground glass joints.

Circle No. 42 on Reader Enquiry Card.



poly-vessels

These expanded polystyrene vessels are used in laboratories and industry for carrying liquid Nitrogen and Dry-Ice. The P.97 size can be used for carrying 'Winchester' bottles of chemicals safely. Supplied with or without carrying handles and lids.

Circle No. 19 on Reader Enquiry Card.

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (*a*) is preferred to e^a if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unaltered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**,1 (1975) and **264**, v, 11 Nov. (1976).

Dependence or autonomy: UNCSTD's hidden agenda

With science-based technology playing an increasingly dominant role in the world economy, the politicisation of next week's conference has been inevitable. The major task is to make it constructive.

WHAT hope for UNCSTD? Delegates currently heading for Vienna, where the United Nations Conference on Science and Technology for Development opens on Monday, carry with them a fat set of gloomy prognostications. A successful conference — and one of the difficulties here is that a single criterion of success is almost impossible to define — still hangs in the balance. One thing is certain, however: not only is UNCSTD the last and possibly the most important of the major UN conferences to have taken place over the past decade — it has also proved to have been one of the most controversial.

There are numerous reasons for the disputes that have frequently threatened to engulf the conference preparations. Firstly there has been the growing recognition that the task of applying science and technology to development is in practice vastly more complex than it was thought to be a decade ago, when theories of technological determinism still reigned supreme in development policy. Secondly, it has become clear that many of the obstacles to this process — such as problems in energy or resource supply, or growing structural unemployment — have been partly due to the way that science and technology have been inappropriately applied in the past. Finally, perhaps less globally significant but important in the international context, has been the extent to which the issues faced by UNCSTD impinge on the existing interests and policies of other UN agencies.

Behind all these, however, is a factor which has received considerably less attention, but which seems destined to play a no less significant — perhaps even a dominant — role in the Vienna negotiations. This is the fact that over the past decade, the global economy has come to depend increasingly on science-based technology as the prime generator of wealth. And that consequently, for both developed and developing countries alike, issues relating to the ownership and control of technology have become as important in a political sense as the use of this technology has become in economic terms.

One result is that for the developed countries the whole issue of science and technology for development has increasingly shifted from the sphere of aid to that of foreign policy. As the developing countries have clamoured for political autonomy, so the interdependence between nations has shifted from the militarily-backed relationships of colonial times to the economic domain. The desire for technological know-how, as well as the conditions under which this is created, bought and sold, have subsequently moved to the centre of these interdependent relationships. In addition, political issues surrounding the impact of technology on society have increasingly taken on an international dimension.

Nowhere have the implications of these developments been more clearly recognised than in the United States. One of the most significant recent trends in foreign policy strategy has been a shift from the aggressive military stance that became so discredited during the Vietnam era, to a style of soft-shell diplomacy emphasising economic cooperation and mutual self-interest. Science and technology, through cooperative agreements, collaborative research ventures, and academic exchanges, have become a central tool in this new aproach. Dr Henry Kissinger was one of the first to point out that problems such as energy, resources, and the uses of space and the sea ranked with questions of military security, ideology and territorial rivalry which had traditionally made up the diplomatic agenda.

The use of science and technology as a tool of diplomacy has received even greater support from the Carter administration. On the one hand it has resonated with the President's own engineering persective on social problem-solving; on the other, it has been actively supported by the US business community as an alternative to more overtly coercive forms of global involvement. Perhaps the most obvious success of this new strategy has been the use of scientific and technical agreement to finesse previously -stalled diplomatic initiatives with the People's Republic of China, a possibility opened up by the new regimes desire for access for US technology. Since then, it has been used extensively to articulate relationships with both developed (e.g. West Germany and Japan), and developing countries (particularly Mexico and Latin America), and the approach has received substantial backing from the US Congress.

To this development must be added another which has also emerged since the deliberations for UNCSTD first began, namely the developing countries' demand for the establishment of a New International Economic Order (NIEO). Both have since come to dominate the perspective from which the developed and the developing countries respectively are approaching the Vienna negotiations. And where conflicts and disagreements have arisen in the preparatory process, many can be traced back to the tension between these two goals. For what the US sees as the use of science and technology in, to use one of Dr Brzezinski's favourite phrases, "the stable management of global change", developing countries see as an attempt to reinforce US hegemony in a new guise. And the latter have also concluded that issues concerning the control of science-based technologies are a key to the restructuring of international relationships envisaged in the NIEO.

Delegates meeting in Vienna next week are not substantially divided on what needs to be done, whether at the level of meeting human needs for adequate food, energy and housing, of increasing research efforts on issues relevant to these and other developing country concerns, or of building up research capacities in the LDCs. The main source of dispute is over *how* these goals should be tackled. And here the central arguments share many of the characteristics of the debates that have taken place within the developed countries over the past few years on the relationship between science and society. Given the problems that have accompanied society's use of science in the past — the pollution of the environment, the heavy imbalance towards military research and technology, the alienation of "scientifically managed" labour and processes, and so on — can better solutions

0028-0836/79/330525-01$01.00

©Macmillan Journals Ltd 1979

be found by revising the responsibilities of existing institutions? Or are the problems endemic to these institutions, and does their solution require, as radical critics would suggest, a more funadmenal restructuring of social and political relationships?

Transposed to the international arena by the UNCSTD conference, the answers being given to these questions seem clear — and frequently in conflict. The developed countries, while not minimising the difficulty of applying science and technology to development, argue that this can still be done most effectively within the existing pattern of international relations. The message they bring to Vienna is that the task requires the appropriate mix of pragmatism and private enterprise with the former intended primarily to fill the holes left by the latter. As one group of US businessmen put it in a report to the States Department, a prime need is "to support and expand the existing system which on the whole has been the source of an unprecedented advance in science, technology and economic development throughout the world."

The developing countries, at least as far as their views have been presented in the preparatory process by the Group of 77 — the "trade union of the poor" according to President Nyerere of Tanzania — see the situation differently. They argue that the political strutures which support the global economy are biased in favour of the rich, industrialised nations, and that a more equitable distribution of bargaining power is central to the NIEO. In the UNCSTD context this means not only building up their own research capacities, but easier (and cheaper) access to the technology already existing in the developed world, and a substantially greater share of control over the global research and development budget.

The developed countries have, not surprisingly, dismissed such demands as "unrealistic". For example, a central objection to the international financing system which the Group of 77 has proposed to support science and technology activities has been the political unacceptability of the developing countries laying down how much the developed countries should contribute to this fund; the latter would prefer to operate through, for example, the United Nations Development Programme, where they can exercise greater control over the size and use of their contributions. In addition, developed countries argue, with some justification, that there is little domestic support for increased aid spending at a time when foreign competition is blamed as one reason for economic recession. Nor is their much enthusiasm for the political goals of the NIEO, whose provisions, according to one US industrialist, "will be a discouraging factor affecting the final resolutions and resulting programming" of the UNCSTD meeting.

In return, there exists a deep distrust among many developing countries about the way that the developed countries conceive the task of applying science and technology to development. The predominent fear is that the types of solution offered, while dressed up as cooperative ventures, will in practice be used as Trojan horses to reproduce precisely those dependency relationships which, they feel, must be broken if a just and equitable global development is to be achieved. Internationally they feel that the continued hegemony of the industrialised nations on research matters implies a dependency which only sanctions patterns of development meeting such nations' interests. Domestically there is concern — voiced more frequently from unofficial rather than official quarters — that solutions designed primarily for their compatability with a global market economy will favour local elites already integrated into this economy, at the expense of the poor who remain marginal to it (apart from providing a source of low-cost labour power). Thus in both cases it is feared that unless sufficient endogenous control is exercised over research and development programmes, however scientifically and technologically appropriate their goals, their benefits will tend to be skewed towards the relatively rich and powerful, and against the poorest and those most in need.

Given these conflicting perspectives, it is perhaps inevitable that the issue of control has become central to virtually all current debates where science intersects with development concerns — what might be called the field of development science policy.

As far as global research projects are concerned, it is already clear that one man's pragmatism is another man's political programme. Issues such as exploring the mineral potential of the sea-bed or attempting to prevent the proliferation of nuclear weapons have become highly charged as developing countries see in proposed procedures attempts to restrict their political rights. On the transfer of technology, the broad parameters of the conflict are already widely known, with the developed countries arguing that technological know-how be respected as the private property of the inventor, and the developing countries preferring to see technology more as part of the common heritage of mankind. Even in the debate over the need for appropriate technologies, developing country scepticism has focussed less on the technologies themselves than on the motives of those who suggest their widespread dissemination.

In sum, what is being challenged at UNCSTD is the extension of the institutional framework and political assumptions which have supported the growth of Western science and technology — the so-called social relations of science — as the appropriate model for applying science to society's needs on a global basis. To the extent that these social relations of science have served the interests of the Western market economies, as well as a number of their socialist counterparts, those who see a global economy operating along the same lines argue that they are appropriate to the wider context. But to the extent that they are seen as presenting obstacles to genuine development, creating unwelcome dependencies, reinforcing inequalities in wealth and power, and condemning those most in need to the economic margins, these social relations will be challenged by critics demanding a far greater control from the grass-roots of the processes leading to both the generation and the application of scientific knowledge.

Where, then, does this leave our hopes for UNCSTD? Putting political realities aside, we could envisage a set of decisions that might include: agreement substantially to increase the proportion of the global R & D budget devoted to development-related topics, say from 5 to 25 per cent by the year 2000 (in line with the Lima target on world trade); agreement to halve the proportion of this budget spent on military research by the same date; agreement that restraints on proprietary technology be substantially reduced where these present a major obstacle to their global deployment; and so on.

Pipedreams and magic wands, however, will have little place in Vienna. At present it would be wrong to expect any quantum leaps in development strategies to emerge (even though these will be hotly supported in the NGO forum). At best we can hope for some agreement on the type of actions that developing countries should take to build up their scientific and technological infrastructures; a limited commitment from the developed countries to reallocate some of their aid funds to R & D objectives; a new focus within the UN system to remind all countries of the importance of science and technology in development strategies; and perhaps preliminary agreement to extend current efforts in fields such as information dissemination and remote sensing.

This may sound pitifully little for an exercise which has taken up so much time and energy over the past few years. But the real gains may be less tangible. The conference secretariat constantly reminds us that, for many countries, merely preparing a position paper for the conference has been a highly instructional exercise. In the same way the conference proceedings themselves may highlight one topic which has been dropped from the explicit agenda, namely the obstacles that obstruct the applications of science and technology to development. (For example through clarifying major areas of disagreement, and analysing the reasons). If no more, delegates will be exposed to the challenge and the difficulties of developing a common frame of international discourse embracing political and technical issues simultaneously. This in itself will do little to change the world; but it is a prerequisite for the issues that need to be negotiated in the decades ahead. □

UNCSTD: what's to be done?

The UN Conference on Science and Technology for Development starts in Vienna next week. We asked a group of scientists, politicians and administrators to pinpoint the most critical action that needs to be taken

The proper place for science in the Third World

by Joao Frank da Costa
Secretary-General of UNCSTD

I AM frequently asked "how are you going to assess if the Conference on Science and Technology for Development is a success or a failure?" It is not an easy question to answer. Obviously, the difficulty in reaching agreement on conference issues should not be the sole criterion. I believe incidentally that there are only three main issues: 'transfer of technology' — which evokes emotional overtones on both sides; the institutional mechanisms for science and technology in the UN system; and, above all, the financial arrangements. They are extremely difficult problems that have been discussed or negotiated without success for decades, and there is no objective reason why, in these times of extreme economic difficulties, dramatic breakthroughs should be considered possible.

Another criterion could be the ability and willingness to arrive at a common agreement on the text in the Draft Programme of Action. For my part, I would have liked to see a Programme of Action containing fewer brackets than the text which resulted from the fifth session of the conference preparatory committee (PrepCom), so that the conference could concentrate on only a few critical issues. The time-table for the PrepCom was however too short, and the exercise undertaken was not much more than a first reading. In addition, it seems to me that the negotiators considered the text as a kind of treaty and not, as they should have, as a general recommendation directed to member states, international organisations, and the UN system; and as a recommendation that still needs to be channelled and endorsed by proper mechanisms like the General Assembly.

In our case, neither of the criteria seem to be entirely valid. I believe that the conference will have achieved at least part of its purpose if it results in the recognition of the specificity and the importance of science and technology as tools for development, and their incorporation into national planning and international programming at all levels. I consider that this purpose has already been largely achieved at the national level. An enormous number of countries (and not only the developing ones) have studied, in the context of the preparations for the conference, the difficult problems involved in the application of science and technology for development. They have also achieved a measure of coordination internally, not only between the different government departments concerned but also between producers of science and technology (mainly the scientific and technological community) and its users (the public in general). Institutional arrangements have been initiated or established, and rudimentary structures have been replaced by more comprehensive and modulated mechanisms for development, at both the national and the supranational level.

The success of the conference could also be judged by the political will shown by member states in providing the tools required to monitor the results of the conference — whether these are programmes of action, declarations or resolutions — and the necessary financial means needed to strengthen the endogenous capacities of developing countries. It is obvious that an international high-level mechanism like an intergovernmental body is needed to monitor the implementation of the results of the conference — otherwise, these would remain on paper. Similarly, the strengthening of the endogenous capacities of developing countries would need some new international financial arrangements, and in the absence of these arrangements, it will remain a pious platitude.

Of course success will only be complete if the specificity and importance of science and technology for development are also recognised at the international level. I believe the second part of the conference (the Vienna conference itself) should be assessed by the importance accorded to those two elements.

The conference is not an end in itself. It is both a reflection on what has been done in the past (rather little I am afraid) and what needs to be done in order to provide each country with a capacity to solve its own problems and to create an international environment conducive to such an endeavour. And it should, of course, also be considered against the background of the New International Economic Order and in the context of the formulation of a new International Development Strategy.

Strengthening the scientific infrastructure

Michael J. Moravcsik

AMONG the various guidelines suggested for UNCSTD the one with perhaps the broadest worldwide support urges that UNCSTD should result in concrete steps to strengthen the scientific and technological infrastructure of the developing countries. Such an aim has a number of advantages:

- it touches on the crux of the matter and is not just a palliative;
- it is relatively low-profiled politically, since many who are reluctant to share specific knowledge or resources are nevertheless willing to share the capability of generating knowledge;
- it is relatively inexpensive and does not require large new lump sum expenditures;
- it can be implemented in a decentralised fashion, thus avoiding the creation of new international or national bureaucracies;
- it brings partial benefits if it is partially implemented, in contrast to grandiose, all-or-nothing schemes.

There are many problems in infrastructure building, and UNCSTD can address only a few of them — it does not matter much exactly which. Science and

technology education of specialists and of the public, inside and outside with technology, and technology with production; and scientific research and technological development: these are all areas in which many specific, realistic, and effective proposals await implementation. Such programmes must involve the direct participation of working scientists and technologists the world over.

The most important aim is to ensure that UNCSTD, unlike the long list of other UN conferences, produces something tangible and operationally useful, even if only on a modest scale.

Dr Moravcsik is at the Institute of Theoretical Science, University of Oregon

A ten-year ban on large and poorly prepared meetings

Ward Morehouse

Now that the final UNCSTD Preparatory Committee meeting is over, it is possible to predict with a modest measure of certainty the likely outcome of the conference — a programme of action filled with platitudinous recommendations for national governments, especially in developing countries, to do more for and with science and technology for development; a new high-level committee and some rearrangement of concerned secretariats at the UN; a charge to the UN Development Programme and the specialised agencies to pay more attention to science and technology in their activities; and possibly some very marginal increse in the resources available from development agencies, mostly by reallocating existing budgets.

In the meantime, the cost of UNCSTD is approaching $50 million — not just the direct UN secretariat and conference costs ($7.8 million) but also the lodging, food and international travel expenses of the 4,000 people expected in Vienna during the last two weeks of August ($6 million), the professional compensation of the 2,500 government delegates and UN officials preparing for and attending the conference ($3.8 million), the host country's budgetary allocation for UNCSTD ($5 million), the five PrepCom meetings ($3.2 million), the preparation of national papers and related preparatory activities of 100 governments and an assortment of UN and other international agencies ($14.6 million) and the 100 or more international conferences and seminars spawned by UNCSTD ($8 million).

The likely outcome of UNCSTD seems marginal in relation to such expenditures. Even if a four-part package involving a $200 million science and technology fund, which is now being quietly negotiated, were to happen (an outside chance), it is not clear whether the result would do more to benefit scientists in North and South who say they are concerned with development or to improve the lives of poor people by bringing them the benefits of science and technology — through, as the principal UNCSTD discussion paper expresses one of the major goals of the conference, "the establishing of a just and equitable social order."

In fact, the real danger of exercises like UNCSTD is that they divert attention from the underlying economic, social, and political causes of human suffering and deprivation by deluding us into thinking these problems can be solved by science and technology alone.

Hence I propose, as one important action to enhance the realisation of the UNCSTD goal expressed above, a ten-year moratorium on large and indifferently prepared international meetings on science and technology for development, and similar global problem-solving conferences, while we search for more cost-effective ways to link the North-South dialogue to meaningful efforts to ameliorate the human condition. The money thus saved can be used in the coming decade to get on with the task of improving poor peoples' lives by whatever means are most appropriate, including — but not limited to — science and technology.

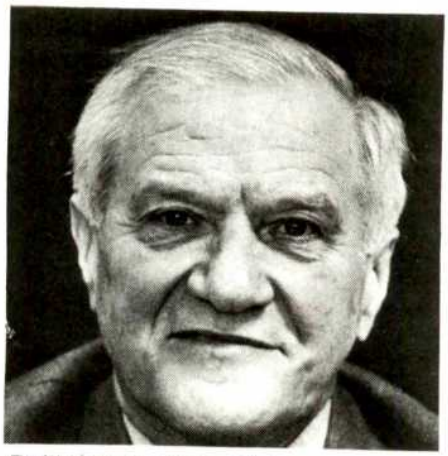
Dr Morehouse is President of the Council on International and Public Affairs, New York

Radical changes in UN procedures and policies

A.B. Zahlan

THE deliberations that underlie UNCSTD revolve around three particular problem areas. North-South relations, internal transformations of developing countries and the UN system as an instrument of technical assistance. Although all three require attention, it is perhaps fitting that UNCSTD should be primarily concerned with how the performance of the UN system could be improved. The UN system is not merely a source of aid; it also diffuses procedures and models that are often copied by the institutions of the Third World. The subject matter concerned with each of these problem areas is extremely complex; the extent of awareness of the specifics of the processes is poor; and the vested interests in the bureaucracies of UN agencies, ministries of Third World countries, the business communities and the governments of industrial countries are such that a stalemate has been attained. This situation is not in the interest of either the world community or the UN system; and it is certainly not in the interest of the Third World.

The efforts so far deployed to effect the



Da Costa: UNCSTD Secretary-General

changes called for by the New International Economic Order and by UNCSTD are too limited to dislodge established practices. The tens of thousands of persons employed in this multi-billion dollar 'aid industry' cannot spontaneously switch off past practices and become pioneers of the New International Economic Order and UNCSTD. The 'aid industry' operates on the basis of concepts of development that originate in both advanced and developing countries, and all these parties must share in altering accepted dogma. The management of the UN system has often attracted attention, but so far the system has not been opened up to provide factual data on its operations, performance and the policy implications of its practices. Yet the technological development of the Third World, along the lines proposed by UNCSTD, calls for radical changes in the procedures and policies underlying the operations of UN agencies. In theory the UN system is subject to scrutiny by member states at the level of the General Assembly, and during the general conferences of the respective agencies. In fact, however, very little of the necessary factual examination and analysis actually takes place at any of these gatherings. Short-term interests dominate, and few of the delegates possess the adequate information to assess the facts. Currently these international discussions are remote from the scientists, institutions and problems of the Third World. It is only through a dedicated concern about the field aspects of science and technology that the debate can be enriched with facts and realism.

The challenge facing the Third World in the UN system today is not to win a vote or to issue a new proclamation, but rather to initiate a process powerful enough to transform the practices of the system. A revitalised UN system has a good chance of accelerating the mobilisation of the internal resources of developing countries. These resources are formidable and all too often underestimated.

Prof Zahlan has been a scientific advisor to the UN (on ACAST) and Professor of Physics at the American University, Beirut. He is presently a visiting fellow at the Science Policy Research Unit, University of Sussex

Dedijer: information revolution

A basic capacity to absorb and create knowledge

Hiroshi Harada

THERE is much that can be said on the topic of 'Science and Technology for Development', but as far as developing countries are concerned it is useless unless they have in the first place a basic capacity to absorb and create scientific and technological knowledge, and to be adept in its use for productive and commercial purposes. This obvious fact seems, nevertheless, to be often overlooked, as is the fact that there is no short cut to acquiring it.

Education is the only universal means for forming this capacity from the innate intelligence available. And in this context, education must not be regarded solely as a process of passing on information and experience, but one which stimulates the curiosity of its recipient and develops a sense of applicability of the knowledge acquired. It must increase practical ability and the powers of observation and communication. It must instil mental self-discipline and ruthlessly maintain standards and integrity in study and research. These — and a willingness to be self-critical — are essential for self-reliance, both individually and nationally.

The process must be started deliberately at the primary level of education. It is too late at the secondary and higher levels, when the sheer weight of knowledge to be acquired can inhibit any burgeoning sense of mastery over it. This applies whether the product of the educational system is a professional scientist or technologist, or a layman. Indeed, an appreciation by the latter of what is involved is essential if the impact of science is to be accepted and the technological revolution necessary for development is to take place. Otherwise, scientists and technologists become, as is seen too frequently in developing countries, elitist and largely ineffectual in the development process.

Prof Harada is a Japanese plant physiologist, currently with UNESCO

Common sense, perseverance and ingenuity

John Ziman

IN the short run, the developing countries are seeking scientific and technological information; in the long run, to make use of that information and to serve their own needs, they will need research capability.

- In the short run, that means material facilities; in the long run, these are merely the instruments of scientific institutions.
- In the short run, a scientific institution is a bureaucratic organisation; in the long run it must grow into a scientific community.
- In the short run, a scientific community is made up of technically qualified personnel; in the long run, it depends on the leadership of its scientists.
- In the short run, a scientist is an expert who has passed the examinations for a PhD; in the long run, this is only an apprenticeship to the profession of research.
- In the short run, the goal of research is to make specific contributions to knowledge; in the long run, it is to exercise curiosity and to solve problems.
- In the short run, problems are often solved by the application of sophisticated, specialised expertise; in the long run this calls for common sense, perseverance, and open mind and ingenuity.

A scientific institution with some capability for research can be set up in about 5 years. Scientific workers with some research experience can be trained in about 10 years. It takes a generation or so of education and cultural change to foster the personal qualities needed to solve practical problems by scientific methods. This path is long and narrow, but it is the only known way. For the developing countries there is no time to lose: they, and we, must start now.

Prof Ziman is head of the Department of Physics, University of Bristol

Breaking the monopoly on scientific knowhow

S. Dedijer

I SEE three threats in UNCSTD to developing countries developing their own capability to find out, to discover, to invent and to innovate in both predictable and unforeseen circumstances. Two of them are strongly backed proposals for deceptive solutions to the problems which arise from the fact that almost all the global scientific and technological output, capability and knowhow is concentrated in only 30 countries, from which the remaining 80% of the world has to import.

The first threat would arise if UNCSTD set up one more UN organisation to 'deal' with the problem, without a critical evaluation of the efficacy of the existing ones. The second threat could come from the search for solutions to the problem in political attacks against 'capitalist dependence' of the developing countries without the realisation that such non-'dependent' countries as the USSR and China are almost colonially dependent on the science and technology of the democratic countries.

The most serious threat is that the developing countries, as shown by their UNCSTD national papers, have done their homework badly. Not one of them seems to have yet discovered the very fact of the new electronic information revolution, or has realised its implications for development. This includes the fact that information democracy — the right and motivation of everyone in a country to obtain, produce, distribute and withold information — is becoming essential for a country's ability to acquire and create scientific and other knowledge and knowhow. Democracy, in other words, is becoming a productive force.

UNCSTD itself offers the delegation from every developing country the opportunity to test critically the approach, the findings and recommendations in their national papers and to apply them creatively for national goals after UNCSTD.

Prof Dedijer is at the Research Policy Institute, University of Lund

Active partnership of Third World scientists

Yongyuth Yuthavong

THE challenge of science and technology today is not to show that it can give rise to social benefits, but that these benefits are produced where they are most wanted — in the Third World. There is an urgent need to direct a far larger part of world scientific and technological activities specifically towards Third World development. Solutions to many development problems have to be sought largely within the developing countries themselves, and their scientists and technologists must be given the necessary means to search for them. Solutions to many problems, for example in the fields of population, nutrition and health, are already known but lack implementation. An integrated approach including all necessary social, economic and political components is needed.

The developed countries have the capacity to find scientific solutions to many basic problems concerning the survival of mankind, and should make more effort in this direction. However, ultimately, effective action in the Third World

depends on the competence and morale of its own scientists, technologists and other colleagues, and sufficient appreciation by its general public of the value of scientific solutions to development.

Support from developed countries could take the form not only of direct financial assistance, but of collaboration between individuals and agencies concerned with issues ranging from basic research to industrial consultation, and the dissemination of packaged technology to an illiterate rural population. In short, an active partnership of Third World scientists and technologists is an important prerequisite for success of development efforts. It is, furthermore, important to make the general public in the Third World — especially the few leaders with so much influence — aware of the critical role of science and technology in development, and to make the necessary tools available.

Dr Yuthavong is at Mahidol University, Bangkok

Three imperatives: food storage, energy, work ...

Guido Brunner

A GREAT responsibility rests on those who will be taking part in UNCSTD in Vienna. They have to make a fundamental choice. They will either be drawn into a discussion of abstract principles of a new international economic order, or — and this is what I hope to see — they will get down to some practical business. The first will merely lead to yet another diplomatic deadlock of the kind we have seen already too often in meetings between the developed and developing world. The other will spark off that real scientific and technical co-operation which is so necessary for the solution of the problems of development.

This is an especially significant time for the conference. Prospects for the world economy are clouded, and governments are worried about the rising cost, and shortages, of energy. For the developing world the three imperatives are: the storage of food, energy and work. The conference must see that the proper scientific and technological resources are freed to contribute to these great tasks.

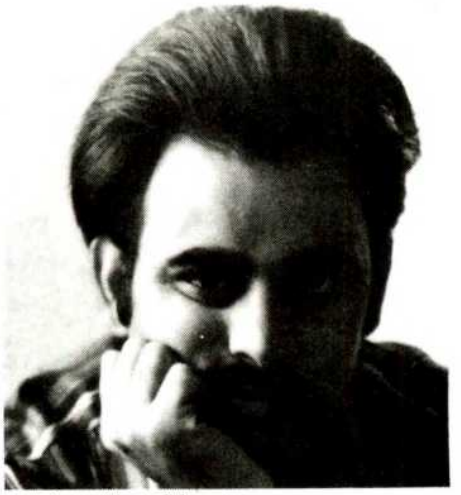
Brunner: fundamental choices

A long term effort internationally and at home will be required if the developing countries are to build up the necessary internal scientific and technological capability. The transfer of technologies from the developed to the underdeveloped is only one aspect of the problem. What is equally important is to establish the means for the developing countries to improve their educational and managerial standards.

The Community and its nine Member States will play their part in this great venture. Our association with 57 developing countries in Africa, Asia and the Caribbean within the Lomé Convention has already enabled us to make a contribution, and the new Lomé Convention will provide us with a framework for offering additional support for scientific and technical co-operation.

Dr Brunner is Commissioner of the European Communities for Energy, Research, Science, and Education

Policymaking should be at the highest level of authority



Antonio Pinilla

THE most pressing need is for a strong, deep and consistent political decision that science and technology constitute essential elements for each state to obtain:

- social integration;
- economic development;
- cultural independence;
- political coherence; and
- administrative efficiency and productivity.

Inadequate knowledge generates racial, social or religious prejudice, frustrating the national integration of countries. Economic growth requires agricultural and industrial mechanisation and rationalisation and these are impossible without a certain advanced degree of scientific and technological development. Payment of duties and royalties make national products uncompetitive in international markets. Economic dependence often generates cultural dependance, so decreasing awareness of national identity. Political and administrative sciences are key solutions to problems concerning political coherence, continuity, administrative efficiency and productivity within a free society.

For these reasons the making of science and technology policy should be the responsibility of the highest levels of authority, such as the president of the Republic (Head of State), parliament and the cabinet. The person in charge of implementing science and technology policy should have the rank of minister of state, or even better, be a full cabinet member.

Sardar: self-confidence

The usual type of problem confronting each cabinet member is something very specific and urgent. Cabinet members cannot afford to concentrate on the scientific and technological aspects of the problems they face. That is why it is critically important that present-day states create national systems of science and technology, giving them the highest level of responsibility and authority to ensure scientific and technological aspects of national plans and objectives, policies and actions are sound, do not include errors or insufficient information, and are adequate and appropriate to each national reality.

Prof Antonio Pinilla is President of the Peruvian Consejo Nacional de Investigacion Cientifica, Lima

Inculcating an appropriate sense of confidence

Ziauddin Sardar

ALL developing starts with the individual, and science development is no exception. The first and the most critical action, in my book, concerns the scientists of the developing countries themselves: every Third World scientist must consciously inculate in him/herself an appropriate sense of confidence. Science can only play its full role in development when the integrity of those who do science is preserved. And this integrity cannot be preserved when the Third World scientists themselves do not have any confidence in their ability to manage their enterprise.

There is a natural corollary to the development of confidence in Third World scientists: confidence in oneself procedes from confidence in one's society, tradition, culture and institution. If someone has confidence in his ability as a scientist and

Salam: 10 times more scientists

his culture and society, then he does not look down on the needs of the society as 'insignificant' and indigenous research as 'inferior'; nor does he apologise away his research efforts to solve local problems or place too heavy a reliance on outside help and consultants and advisors. Furthermore, a scientist with confidence in himself builds up confidence in his colleagues and does not feel threatened by younger scientists. Nor does he articulate the desire to block the paths to full realisation of those who have potentially more to contribute to science development.

As far as I am concerned, science development in the developing countries begins and ends with the confidence the Third World scientists have in themselves, their society and the science that they practise.

Dr Sardar is at the Hajj Research Centre, King Abdul Aziz University, Jeddah

Local scientific committees are too small

Abdus Salam

I HOPE the conference can focus on and initiate action on the following important area. Any declared intention of applying science and technology to development is — and will remain — meaningless until the developing countries build and deploy indigenous scientifically and technologically trained communities. At present, however, such communities simply do not exist, or their sizes are tenths or hundredths of what is needed. Their direction and deployment must be the concern of scientists and technologists themselves, and not of the economists and bureaucrats of national and international planning commissions.

It must be realised that whatever priorities the countries set themselves (food production, mineral exploitation, transport, health, manufacture or even defence), a meaningful application of science and technology needs commitment; is not cheap in money, men or time; and it brooks of no magic formulae.

Turning to the reciprocal role of developed countries, we note that the theme of world development has been woefully neglected by the scientific and technological communities of the developed countries, who have made little organised effort to help in this task, nor have they collectively shown any great vision. The same applies to their state agencies.

In addition, the international funds at the disposal of bodies like ICSU — or even UNESCO — for the development of science and technology for global concerns are pitifully small. (The entire UNESCO budget — not to restrict it to what is spent on science and technology — is smaller than that of the Ford Foundation). These international funds need to be increased by at least an order of magnitude.

Prof Salam is Director of the International Centre for Theoretical Physics, Trieste

A large debt remains for past exploitation

Joseph Hanlon

THERE is a need for a 'new scientific order', like the new economic and information orders, which attempts to break the stranglehold of the developed over the developing nations. Scientists in developed nations must realise that the science gap has not come about by accident. During the past 200 years of scientific progress, most Third World nations were colonies which were not permitted to develop an independent scientific capability. Small wonder, then, that there is a gap now.

The challenge today, especially for UNCSTD, is that the developing nations are working hard to maintain and widen that gap. The brain drain continues, with the developed nations sucking the brightest scientists into their companies, health services, and universities. Patent laws are now being used to block Third World research into key areas such as alternative energy. Journals and scientific societies, controlled by developed world scientists, define 'good' science as that which is of interest to developed nations. Tied aid ensures that experts and equipment come from such a wide variety of countries that even the most talented local scientist cannot digest and control the results.

All of this ensures that in those scientific areas which are of most importance to the developing nations — health, energy, ecology and geology — the expertise and control will remain with the developed nations.

UNCSTD can help to end this exploitation. But it will require the realisation in the developing nations that they must stop bowing to the demands of journals and aid agencies in the industrialised world. And it will require that scientists and science policy makers of the developed world understand that a large debt remains to be paid for past exploitation, and that a way of repaying is to provide increased aid — not for what they think the Third World needs, but for what local scientists and policy makers feel is required.

Dr Hanlon is a development journalist

Loosen the grip on proprietary rights in technology

Jose Goldemberg

THE most critical actions necessary to improve science and technology in the developing world are probably beyond the powers of UNCSTD, or of the United Nations.

Science, especially technology, does not flourish in the Third World — not because of incompetence amongst the people involved (although that exists too) — but because it is not really needed in the present model of development being followed in most of the Third World. Machines, technical expertise and a powerful marketing system coming from abroad inundate the developing countries, ministering to some of the needs of the people, creating others and above all generating a craving for the comforts of modern civilisation as defined by the industrial nations.

There is little that science can do to interfere with this situation, because most of the science needed exists already, and there are no fundamental new discoveries that could change the situation or the climate in which science could flourish in the Third World.

Technology, however, has to be adapted, in many cases to local conditions (of temperature, humidity, and so on) and to local fuels and materials. Native technologies have a role to play there, but in general technology is imported.

The most critical action to take in my view would be to loosen the grip on proprietary rights in technology. If these were made available and essentially free, local industries would have more room to move and more scientists and technologists would be needed to make choices and develop missing links. One thing that could accelerate this process would be to have international funding institutions which preferentially support projects that use as much native technology as possible.

Dr Goldemberg is at the Universidade de Sao Paulo, Brazil

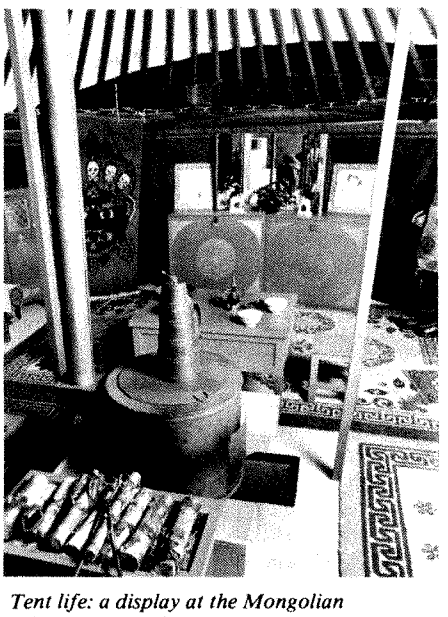
Soviet aid: a two-way traffic

The eastern bloc's relations with the Third World stress 'real reciprocity'. **Vera Rich** reports

Science and technology transfer from the Soviet Union and other Comecon countries to the Third World is seen, not surprisingly, somewhat as an extension of such transfers within the bloc itself. That is to say, it is viewed not as "aid" — a word properly reserved in Soviet terminology for *ad hoc* measures such as the recent earthquake relief to Yugoslavia but as an essentially reciprocal process. (The official name of Comecon is the Council for Mutual Economic Assistance).

One interesting outcome of this approach is the attitude to "intermediate technology". The long-term plans of Comecon aim at integrating the economies of the member states, hence there is clearly a pressure to bring such countries as say, Hungary and Bulgaria, from a peasant-agrarian to an agro-industrial economy in the shortest possible time.

At least, this is the case in the production sector. The current Mongolian exhibition in London suggests that, although the Mongolian People's Republic boasts a state university, an academy of sciences, polytechnic, medical research institutes, a flourishing pharaceutical industry and a major programme for the exploitation of mineral resources, a significant proportion of its population still lives, by choice, in the traditional *ger* or felt tent, though, on the outskirts of the capital, Ulan-Bator, gers are frequently fitted with such modern conveniences as electgric light and television.



Regarding the third world, Soviet commentators stress that the bulk of what they offer is not the "relatively primitive mechanisms and implements which, in the opinion of some foreign theorists, are the most appropriate to the present requirements of the 'third world' countries", but "modern technology . . . which can contribute to the developing countries' mastering of modern scientific and technological achievements". Similarly, when co-operating with the developing countries, the Comecon countries have tended to follow current practice within the bloc as far as know-how is concerned.

As a result, the transfer of technological documents to the third world, originally free of all but incidental costs, has increasingly become replaced by the sale of know-how and licences (usually against long-term credits), and special trading organizations have been set up in the various Comecon countries to handle this. These include *Litsensintorg* for the Soviet Union, *Polservice* for Poland, and TESCO for Hungary.

Hungary is a particularly interesting case of such co-operation, since, until recently, it was itself eligible for aid under the United Nations Development programme. TESCO, the Technical and Scientific Co-operation Organisation, was founded in 1962, and at present operates co-operation agreements with 57 developing countries. One of the directors of TESCO, Mr Istvan Orosz, told *Nature* recently that Hungary cannot offer such assistance free, although sometimes it may be provided at basic costs. Another director, Mr Sándor Derzsi, stressed that in the case of countries which have recently been "liberated from colonialism" the main form of co-operation is the sending of Hungarian experts (in all, nearly 1000 annually), whose salaries are, if necessary, paid by the Hungarian government.

As the countries develop, he said, the form of co-operation can change. This was the case with Cuba, for example. Originally Hungarian experts went to Cuba, and Cuban trainees studied in Hungary. "But now we have bilateral connections and joint research projects with various Institutes". Cuba had taken 10 years to reach this stage. "But Iraq, Algeria and Nigeria have an economic basis", he added, "so they can reach the second stage more quickly".

This "tendency towards real reciprocity", said Mr Orosz, is typical of TESCO. Mexico, for example, has developed its own research in the growing of maize, a crop of considerable importance to Hungary also. A similar pattern, he explained, can be seen in Hungarian-Soviet co-operation. From 1948, when Comecon was established, until well into the 1960s, Hungary was largely the recipient. "We received some technology from the Soviet Union, and had our experts trained there. We did have some co-operation, but it was on a 20-80 basis." By the mid-1970s, however, some 50 to 60 Hungarian research institutes were engaged in joint ventures with their Soviet opposite numbers.

Tent life: a display at the Mongolian exhibition now showing in London

Basic research and exchanges involving whast Mr Orosz described as "concrete scientific themes" come not under the auspices of organizations such as TESCO, but that of the relevant Academies of Sciences. Nuclear research, for example, belongs here, and so does the Comecon space programme *Interkosmos*. The latter, it appears, (*Nature*, **280**, 94-95) is financed overall by the Soviet Union, with the other member countries paying only for their own experiments. This would explain why Vietnam, which joined Comecon last year, could this spring send two cosmonaut candidates to Baikonur for training, although the Vietnamese economy is in such an urgent state that 75% of the proceeds of this year's *Subbotnik*, the Saturday in April when Soviet citizens contribute a day's work for the good of the economy, are to be devoted to Vietnam.

Many co-operation projects bring the Soviet Union and other developed Comecon partners gains in raw materials. The Comecon survey of Mongolia, for example, will allow Mongolia to increase its exports of minerals — presumably within the bloc. Some projects such as the Afghanistan and Trans-Iranian gas pipelines were constructed on a "buy-back" basis. Soviet oil and gas prospecting in India, Afghanistan and Pakistan, or coal prospecting in Nigeria might well be compensated in some of the product. On the other hand, recent agreements to build a hydroelectric station in Costa Rica or develop the cotton and wheat production of Angola will bring a less immediate return to the Soviet Union — except in good-will.

For it is impossible to assess the impact of Soviet/Comecon assistance to the Third World without considering political implications. Soviet histories of the United Nations intended for home readership present the Soviet delegates as engaged in a "struggle" for "progressive principles of technical assistance". The more moderate language of a Soviet report to the UN notes that "Economic independence of the developing countries is unthinkable without their scientific and technological liberation from imperialism . . .".

Unfortunately, goodwill projects can be affected by subsequent political changes. For many years, the Aswan High Dam, with its associated hydrotechnical projects and irrigation schemes was regularly quoted as a prime example of such an undertaking. Last May, however, on the fifteenth anniversary of the "changing of the course of the Nile", Moscow Radio's Arabic service could only speak sadly of "some persons" who are now striving to make the Egyptians forget the Soviet contribution to this project. □

Agroforestry: new hope for subsistence farmers

David Spurgeon reports from the first Conference on International Cooperation in Agroforestry, held in Nairobi last month

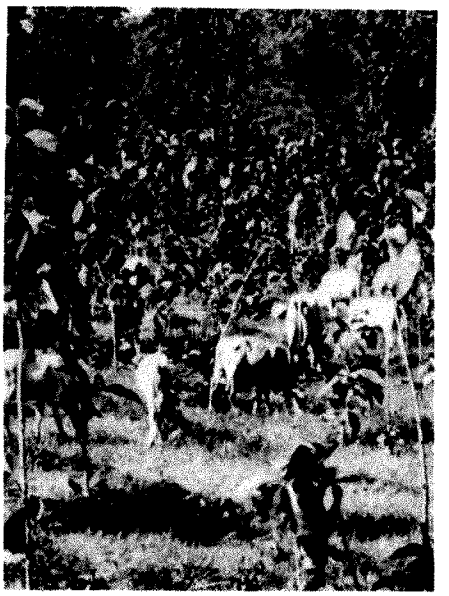
THE ancient practice of shifting cultivation has for many years been severely criticised by agriculturalists and foresters because of its destructive effects on both land and forests. Shifting cultivators fell and burn forest land, then plant food crops and raise animals and later move on when soil fertility drops. After a period of bush fallow, they return to the same site and repeat the process.

Historically, soil fertility was maintained first through the nutrients returned via the ash after burning, and later through natural processes during the long fallow periods. However, as population and economic pressures have increased, fallow periods have become progressively shorter and the land ever more exhausted of nutrients.

Within recent months, however, foresters and agriculturalists have been looking at these traditional practices with new eyes. Scattered but convincing evidence exists to show that the integration of trees, food crops and animal husbandry on the same piece of land can increase total productivity while preserving the ecosystem. Such a system could not only improve the way of life of the 250 million people in developing countries who depend on shifting cultivation for survival, but could help save the world's tropical forests from destruction. The name given to this approach is agroforestry.

The first Conference on International Cooperation in Agroforestry, held in Nairobi, Kenya, at the end of last month, was an indication of the widespread interest the concept has generated: delegates from 31 countries and eight international agencies attended. They strongly endorsed agroforestry practices, particularly in marginal or degraded areas where agriculture alone is not productive. They urged the extension of research into agroforestry systems throughout the developing world. And they recommend the adoption of education, training and extension programmes by appropriate institutions.

Much conference discussion was devoted to definitions of agroforestry. ICRAF's definition is a "sustainable land management system which increases the overall yield of the land, combines the production of crops (including tree crops) and forest plants and/or animals simultaneously or sequentially on the same unit of land, and (which) applies management practices that are compatible with the cultural practices of the local population." It was considered by some as not comprehensive or precise enough. No agreed-upon definition emerged: the conference left it to ICRAF to hammer out a final version.



The lack of an adequate definition did not inhibit enthusiasm for the practice itself, however. Numerous examples were given of its benefits. One, from Soekiman Atmosoedaryo, president of Indonesia's state forest corporation, Perum Perhutani, was a programme that aims at developing forests not only as providers of wood and cellulose and protectors of the environment, but as sources of food, animal feed, honey, medicinal herbs, pine resin and natural silk. The programme, which involves growing rice between young forest plants, has raised paddy production from 0.7 tonnes per hectare to 1.8 tonnes within two years.

The director-general of the United Nations Food and Agriculture Organisation had told the 1978 World Forestry Congress in Jarkata that the forest areas of developing countries are being destroyed at the rate of 16 million hectares a year. At the Nairobi conference, a paper by Professors Jon Morris and Keith Openshaw of the University of Dar-es-Salaam translated this into starker terms: "Every three years an area of forest is being lost that could supply in perpetuity the wood raw material requirements of 480 million people — enough to meet all the requirements of the African continent!"

Peasants and subsistence farmers in developing countries are on the horns of a dilemma, according to Morris and Openshaw. On the one hand population pressure, rising expectations and faulty agricultural practices are cuasing them to destroy the woodlands. On the other hand, they need the products of the forest for cooking, heating and shelter, so they must preserve the trees. "A combination of agricultural practices are causing them to most logical way to do this," they said, "— having one's cake and eating it. And yet it is not universally practised."

Morris and Openshaw examined the economics of growing trees for fuel and poles together with agricultural crops in Kenya, and concluded that it "appears to be a sound economic proposition". The cost of planting a half hectare of trees would be only 740 Kenya shillings (about £49) over a 10-year rotation, with an average yearly cost of 70 Kenya shillings ($4.7) while the financial yield would be approximately 12%, "well in excess of the minimum 8% that the Tanzania government expects from projects it invests in."

They concluded: "The farmer by growing his own wood products guarantees his energy, building materials and fencing requirements as well as improving his microclimate, soil fertility, fodder and food supply. He may even produce a surplus to earn cash income."

Integrating trees and animals: part of Indonesia's forest corporation

One of the surprising revelations of the conference was the extent to which agroforestry practices are already being carried on throughout the world, and the amount of research already being conducted. Countries in which agroforestry is extensively used include Indian, Bangaldesh, Sir Lanka, Thailand, and the Philippines in Asia; Trinidad, in the West Indies; Mexico and Costa Rica in Central America; Argentina, Brazil, Chile, Colombia, Ecuador and Peru in Latin America; and many countries in Africa, including some in the Sahel.

Agroforestry research programmes were described in a number of these regions. Dr Gerardo Budowski of Centro Agronomico Tropical de Investigacion y Ensenanza (CATIE), Costa Rica, said "agroforestry has made an imposing start in the region (Central and South America), and will undoubtedly move ahead, particularly in wet areas where trees seem to be particularly indispensible ingredients. However, at this stage, it appears that scientists and administrators are more moved by wishful thinking than hard evidence. The task of designing appropriate technologies for specific ecological, social and economic conditions still remains to be done."

Dr Budowski's concern about the need for hard data was a central one at the conference. Yet some projects are already trying to obtain it. Besides those undertaken by CATIE, one was described by Abdul Malik Choudhury, deputy chief conservator of forests for Bangladesh. A pilot scheme is underway there to settle 300 families through agroforestry practices. Each family is given five acres of land on which to grow bamboo and practise

0028-0836/79/330533-01$01.00

©Macmillan Journals Ltd 1979

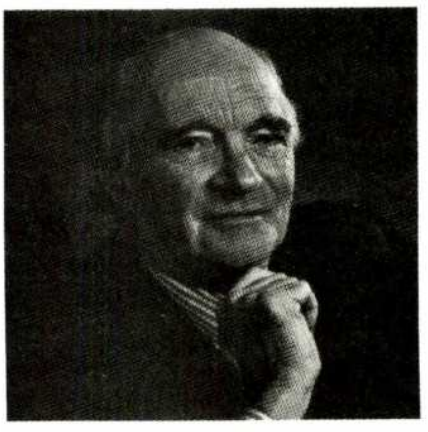
horticulture. They are paid for land clearance and given loans for inputs. A target of 9,000 acres is to be settled in this way in ten years, with an assessment after five years and an ultimate goal of 2.5 million acres if results of the pilot scheme are positive.

Although enthusiasm ran high for agroforestry, many voiced concern that too much might be expected of it, and were cautious about the prospect of its acceptance as a new discipline. One question raised was whether promotion of agroforestry practices would condemn subsistence farmers to a life of poverty. Dr King, whose agency went into operation only a year ago, answered that "Without inputs (eg fertilisers) they are condemned to a life of misery and mere subsistence. Don't think that if we could get them inputs we would be sitting here. You can grow anything anywhere if you have the money. It is precisely because farmers will remain at this level that some of us believe we could help them in a way that might not be so costly.

"Agroforestry is not the answer to all social problems. But I really think that, given the problems in some of these countries, it ought to be tried." □

Peer seeks to improve UK animal research law

LORD Halsbury's Animal Protection Bill successfully passed its first reading in the House of Lords on 16 July. Sometime after the start of the new parliamentary session on 23 October, it will receive its second reading. If it survives that hurdle, it will then be the subject for discussion of a Lords Select Committee before it is given its third reading and eventually handed over to the House of Commons for adoption as law — a procedure which could take up to two years to complete. Earlier this week, the Research Defence Society — which exists to promote the need for research with animals — held a press conference to mark the Bill's first successful reading.



Lord Halsbury, who has been President of the Research Defence Society for twenty years and has been interested in the use of animals in research for much longer, decided to formulate and sponsor the new Bill about one year ago. A series of events had persuaded him that it was time the government "took over its responsibility" to research and opposed the allegations of cruelty to animals in many laboratories being expressed in some of the tabloid newspapers. His Bill is intended to replace the increasingly criticised Cruelty to Animals Act of 1876 as the main piece of UK legislation for ensuring the protection of laboratory animals.

Two events last year convinced Lord Halsbury that the 1876 Act — which, he says is "mostly criticised by those who don't understand it" — needed revising. One was an address to the Annual General Meeting of the RDS in which the speaker expressed his growing distaste at experimenting with animals. ("I realised that I felt that way myself", says Lord Halsbury). The other was last year's Labour Party conference which was attended by a number of slogan bearing anti-vivisectionists and resulted in the Labour government promising to set up a Royal Commission on Animal Protection to look at all aspects of animal rights (a promise which went by default when Labour lost the last election). Setting up a Royal Commission to tackle the problem would have been like "using a sledge hammer to swat a gnat", according to Lord Halsbury. The problems of animals on farms, in slaughter houses, in transit, in laboratories and as pests are all very different. In attempting to cover all five areas, the Royal Commission would be trying to be a "council of perfection".

In spite of his belief that the 1876 Act does work reasonably well, Lord Halsbury has come to the view that there is a need for more restrictive legislation. "Scientists must realise that they cannot live on the 1876 Act forever", he says.

His main criticism of the old Act is that it is too narrow; so his Bill is designed to extend the scope of legislation beyond vertebrates to include other species as and when protection is considered necessary "in the light of advancing scientific knowledge of the nervous systems of such species". Current legislation caters well for "cuddlesome pets". "But the octopus doesn't get protection. This is a highly intelligent creature — at least as intelligent as some of the minor vertebrates." Arthropods, such as crabs, also do not receive protection under the 1876 Act. "Do they have pain nerve endings under their shells?". The incorporation of new species on to the protected list would, under Lord Halsbury's Bill, be up to the relevant Secretary of State.

The new Bill would also extend the definition of a laboratory and an experiment. "All laboratory usage is included, even a green field". The word experiment has been deliberately excluded from the text of the Bill and replaced by "procedure" which should increase the number of animals entitled to protection. Lord Halsbury expects that the effect of this broadening of scope will be to increase the number of institutions applying for licences to work with animals.

Lord Halsbury: seeks support of scientists

The overall philosophy behind the Bill is not very different from that behind the 1876 Act. After all "nothing that's said now is any different from what was said then", according to Lord Halsbury who has been studying old Hansards to find out the arguments in vogue before the introduction of the first Act in the 1870s. There are differences in some of the detail, however. For example, the Bill gives power to the Secretary of State to "make regulations to control the procurement, breeding, transport, accommodation, management, veterinary supervision and care of animals for laboratory use". It also gives stronger powers to inspectors, including the right to enter premises licensed under the Bill and to order the killing of any animal thought to be suffering unduly. The Secretary of State would also be required to publish a 'guide to good laboratory practice' which would include advice on the use of alternatives to experiments with animals. The Advisory Committee to the Home Office would be extended to include advising the Secretary of State on novel or controversial procedures and on the incorporation of new species.

For the success of his Bill, Lord Halsbury believes that he must have the support of the scientific community. The Select Committee stage at the House of Lords should provide scientists and others with the opportunity to study the Bill and express their opinions. But the Bill should only be a "little more restrictive" for scientists ("there are very few people who do experiments on octopus"). The anti-vivisectionists, however, are bound to be critical. "The militants will misrepresent the Bill. They will say that the word 'experiment' was cut out to disguise what scientists are doing, whereas procedure has been used to get animals protected".

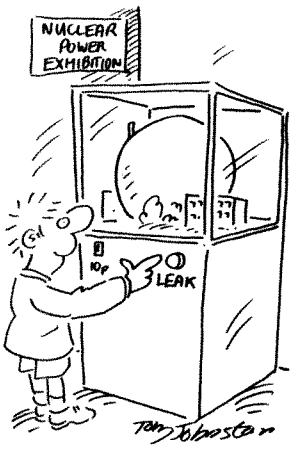
The UK has amongst the toughest legislation of any country on the protection of laboratory animals and Lord Halsbury believes that it should take a lead in the Council of Europe's deliberations to formulate European guidelines. "The government says let's wait and see what the Europeans do. But the UK should take the lead. I make up my own mind first and other people's later". **Judy Redfearn**

news in brief

Tropical legumes can aid Third World economies: A report issued by a panel of the US National Research Council describes almost 200 species of underexploited tropical legumes that could prove valuable to "the economies of developing countries." The legumes, which include root crops, pulses, fruits, forage crops, fast-growing trees, luxury timber and fibre and gum producing legumes, can reduce dependence on costly chemical fertiliser, widen the range of agricultural products and increase the production of food proteins. Of the thousands of known leguminous species only 20 are used extensively. The 200 plants selected by the panel could produce edible oils, nutritious forage, paperpulp and firewood as well as resins, tannin, spices and food. The panel notes: "Of all plants used by man, only the grasses are more important than the legumes. However while enormous resources have been expended in recent decades on grasses like rice, wheat, corn, sorghum and barley, among the legumes only soybeans and groundnuts (peanuts) have received much attention." The report is critical of the 'green revolution' for not having decreased protein malnutrition in the Third World and calls for an equal effort to be spent on the production of pulses which "could quickly eliminate protein malnutrition for the immediate future."

J.P.M. Brenan, Director of the Royal Botannic Gardens at Kew near London and a member of the NRC panel cautions that there are difficulties to be solved before legume production becomes a reality. These include studies to determine whether plant breeding techniques can work to select good strains, whether the plants can be adapted to arid and semi-arid tropical environments and whether the plants could become pests when introduced to new areas. "It's a very large programme and we are too small and too poorly funded to carry it out quickly" he said.

UK research and development funding falls below 1964 levels: Research and development expenditure trebled in the UK between 1964 and 1975 but fell in real terms, according to an article in *Economic Trends,* published by the Government Statistical Service. Using 1975 price as a base, the article says £2,200 million was spent on R&D by government and industry in 1964 but only £2,151 million in 1975. The number of people employed in R&D has also fallen. In 1967, industry had 219,000 researchers compared with only 180,600 in 1975.



R&D expenditure peaked at the end of the 1960s and steadily fell from 1970 to 1975. Industry's expenditure fell particularly sharply in the early 1970s, whereas central government R&D expenditure rose between 1970 and 1975 but then fell from 1976-1977. In volume terms, however, R&D carried out by the government changed little, because between 1970-1975 the government financed more R&D actually carried out by other sectors. Defence research suffered the biggest cuts in central government spending falling from 0.86% of the gross domestic product in 1964 to 0.16% in 1977.

Wider brief for cholera lab: The Cholera Research laboratory in Bangladesh has been re-named the Internatioanl Centre for Diarrhoeal Diseases Research, putting an end to last year's rows over the laboratory's future. Research and training on the diarrhoeal diseases and their related nutrition and epidemiology will be carried out at the centre, and finance and organisation will be multi-national. David Bradley of the London School of Hygiene and Tropical Medicine said he was pleased the work done at the Cholera Research Laboratory would continue. "It is a lab which has done superb work in the past and much of our knowledge of cholera has come from there. Dacca is a good place to have the new centre. There are over 100,000 people to work on there in an area where cholera is highly endemic." The laboratory had been reconsitituted on a firmer international basis in order to expand its remit and funding.

China begins construction of its 50 GeV synchrotron: Surveying has begun near the Ming Tombs, Changing County, Beijing (Peking), for construction of China's first 50 GeV proton synchrotron. A preliminary design for the machine has been completed after several years of effort by 500 scientists and engineers in China. The final decision to build the facility was announced by vice-Premier Fang Yi in March 1978.

Since then about 100 factories and scientific institutions have been producing parts for the synchrotron. The Ministry of Metallurgy and the first and fourth machine-building industries, the High Energy Physics Institute of the Chinese Academy of Sciences and the Beijing Electrical Heavy Machinery Plant have already produced some of the required equipment.

China continues to push towards increasing its scientific and technical relationship with the West. At the Canton Trade Fair in April, China offered its nuclear instrumentation for sale abroad for the first time. A total of 14 equipment categories including instruments for handling radioactive isotopes and for measuring radioactivity, and remote handling devices, piping and valves for nuclear industry are being sold by the China Nuclear Equipment Corporation.

UKAEA launches informational campaign: The UK Atomic Energy Authority is opening a nuclear power exhibition in London beginning on 20 September for two weeks. Designed to take the "myth and mystery out of nuclear power" the exhibition will show that nuclear power is a tried and proven technology now providing 14% of the UK's electricity at a price that "industry can afford." A UKAEA official said the exhibition will present the facts about nuclear power with no need for a "recourse to opinion." The official told *Nature* that there will be no information about Three Mile Island in the exhibit as "UK reactors are not of that type." The Secretary of State for Energy will open the exhibition and scientists and engineers will be on hand to answer questions. A large number of schools is expected to organise parties to the exhibition.

NRC invites public submissions on Three Mile Island: The US Nuclear Regulatory Commission is inviting the public to help it decide a complicated legal question of liability in the Three Mile Island accident of last April. According to the provisions of the Price-Anderson Act claimants for damages caused by an "extraordinary nuclear occurrence" do not have to prove negligence on the part of the company if there was (a) a substantial release of radiation off-site and (b) there were substantial off-site damages. If the commission were to make these findings a claimant would only need to prove injury or damage, the value of the damage and that the damages were caused by the accident. If the commission does not make these findings, the claimant has to prove not only damages but also that the company was negligent. NRC staff have given preliminary advice that the radiation released appears to be several hundred times less than the criterion set in the Act.

Eruption over Atlantis: Soveit oceanographer Andrei Aksenov announced recently that Western news agency reports last March of Soviet claims to have discovered Atlantis were a "misunderstanding". The underwater photographs which gave rise to the reports (of walls and buildings) now prove to show Mount Ampere, a submerged volcano some 380 km south west of Portugal.

Dangers of low doses of radiation

SIR, — David Dickson's account (19 July, page 180) of the controversies surrounding the BEIR III report is evidently a fair and unusually competent job of science reporting. However, it should be made clear that the disagreement on the validity of the "linear hypothesis" when applied to carcinogenesis by low LET radiation does not, strictly speaking, concern the "filling" of a "gap". This terminology might be interpreted to indicate an interpolation while there is in fact the need for (much more uncertain) extrapolation. It is the magnitude of the risk at about 0.1 Gy (10 rad) that is in dispute. As stated by Dickson, there is agreement on even greater uncertainties at lower doses. I, for one, could not object to various surmises (including linear extrapolations) on what might happen below that level in view of the virtual absence of acceptable data on the carcinogenetic effects, if any, of such small doses.

By contrast, information on high LET radiations, and especially the data for Hiroshima, where neutrons plainly posed the principal hazard, indicates approximate linearity down to doses less than 0.1 Gy.

It should also be borne in mind that any fit of the data by linear or quadratic functions is probably at best a first approximation. Animal experiments show complicated — and sometimes inverse — correlations between radiation dose and carcinogenesis which vary not only between species and strains, but also between types of cancer. It would seem unrealistic to assume that the same does not apply to man.

HARALD H. ROSSI

Nautilus records Earth's second moon

SIR, — I quite understand the need to close the debate on the fascinating Kahn-Pompea-Runcorn dialogue concerning the possibility that *Nautilus* has quietly recorded the lunar recession rate through the ages (31 May, page 452). However, it should be noted that (as in many debates) the participants, including *Nautilus*, may be arguing from different premises. That is to say, while Pompea, Kahn, and Runcorn are clearly discussing our present moon, let us say Luna, *Nautilus* may in fact have recorded the recession of a sister moon, let us say Selena, from Ordovician until rather recent geological time.

If Selena had been in orbit at 12 Earth radii in Ordovician time, as Pompea and Kahn propose for Luna, she could have dominated the *Nautilus* recording apparatus even with a mass much less than her sister Luna, who could well have been orbiting far out near her present position of 60 Earth radii. Perhaps a later Precambrian continental emergence had greatly increased tidal fricition, so that light-weight Selena, receding from the Earth at the required ten-times greater rate than that of present-day Luna, finally approached her sister too closely, and was either devoured by collision or ejected to the firmament. In any event, a small Selena could have orbited the Earth more closely, and have retreated much more rapidly than her larger sister, without dumping the excessive heat noted by Runcorn into the Earth-Luna system.

If Selena vanished before mid-Tertiary, then Runcorn's objection that there is no record of the maxiumum 33-day month which Luna should have produced at 45 Earth radii is of no concern; Luna would have been far beyond that orbit when she took over regulation of the Nautilian cycle, leaving every vestige of Selena forgotten except for a few shells and perhaps a very-young lunar mascon.

It is worth noting that H. Alfven and G. Arrhenius (*Evolution of the Solar System*, NASA, 1976) have proposed, by analogy with the Martian satellites, that Earth once had a second moon at a predicted orbital distance of 13.5 Earth radii, very close to the inferred Nautilian Ordocician value of 12. Perhaps Selena finally perished simply because Earth had oceans of water; the persistence of two Martian satellites may thus mean that Mars has never had an ocean at all.

HARMON CRAIG

Scripps Institution of Oceanography, La Jolla, California, US.

Nuclear power: an evil necessity for some countries

SIR, — In a letter under the title "Nuclear power does not lead to nuclear weapons" (5 July, page 10), Mr Greenhalgh, speaking for the nuclear lobby group "A Power for Good", argues that there is no direct link between peaceful nuclear power and nuclear weapons. It is tragic that in this day and age such absurd views should be advanced, which fly in the face of convictions held by the majority of nations. The Non-Proliferation Treaty and the safeguard systems of the International Atomic Energy Agency are the best evidence of the concern which people all over the world have for years felt about the link between nuclear power and nuclear weapons. More recently, and in recognition of the weaknesses and shortcomings of the NPT and the safeguards systems, a number of new initiatives were taken. The London Club was set up to provide additional guarantees. The International Nuclear Fuel Cycle Evaluation, with 56 nations participating, is still studying ways and means of reducing the danger of proliferation arising from the use of nuclear power. In the United States a special act was brought into being for the same purpose. Why would this enormous effort be needed if there were no danger of nuclear power leading to nuclear weapons proliferation?

Mr Greenhalgh bases his argument on past history, that countries developed nuclear weapons before starting nuclear power programmes. But the fact that something has not happened in the past cannot be used as an argument that it will not happen in the future, particularly if the opportunities for it were greatly increased. One of the chief characteristics of beings endowed with thinking power is that they can look ahead, anticipate possible trouble and take steps to prevent it.

A nation could, of course, obtain nuclear weapons by means other than power reactors, but the existence of one danger does not justify the introduction of another danger. Moreover, the setting up of a nuclear power programme, while not being a pre-requisite, is the most likely route to the acquisition of nuclear weapons, because the technology and the materials become legitimately available to a nation possessing nuclear facilities, including a reprocessing or an enrichment plant.

Mr Greenhalgh points to the existence of 100,000 MWe of nuclear power in the world as evidence of no direct link with nuclear weapons, but he forgot to add that this contributes less than 1% to the world's annual energy consumption. The situation would be radically changed if nuclear power increased by two orders of magnitude, as it would have to do (to meet the energy needs of the developing countries) in order to become the chief source of energy as envisaged by Mr Greenhalgh and his ilk.

Fortunately this is not likely to happen. The danger of proliferation, together with other well known negative aspects of nuclear power, as recently illustrated by the Three Mile Island accident, have now convinced public opinion that, at most, nuclear energy should be considered an evil necessity for some countries. Except for those with a vested interest, very few now believe that nuclear energy is a power for good.

Democracy cannot be defended by security police

SIR, — " 'Just imagine yourself sitting there below the judges' table . . . squashed like a lemon'. 'Just tell us, are you a communist?'. 'What do you think of the GDR?'. 'If as a christian you are an anti-fascist — should you not be anti-communist as well?' 'As a christian, you say love your neighbour. But how about the fascists?'."

These quotations come from the official report mentioned in *Nature* (31 May, page 363), which to your correspondent has been "cleverly invented by leftist totalitarians". They are in fact excerpts from the questions asked of Heinrich Haberlein, a pacifist who was found by the constitutional courts unfit to be a teacher, because "while not belonging to those groups hostile to the constitution, his employment could be rejected, if he, while not actively combating the free and democratic constitution, could be reasonably supposed to be simply indifferent towards the latter." (Page 37 of the DGVT report). I suppose that this is an example of what your correspondent calls the 'right to select', and it is of little surprise that the German Society for Behaviour Therapy's report carries the results of this policy.

Your correspondent seems to miss the point that you don't defend democracy by creating a vast security police to hound out 'totalitarian radicals' because you intimidate and pollute its concept.

Stops and starts in microtubules

from Dennis Bray

THE conventional wisdom that microtubules run the entire length of nerve axons and dendrites probably comes from a paper by Weiss and Mayr (*Acta Neuropath.* supp V, 198; 1971). On page 200 these authors conclude that "each tubule is a single unitary entity, extending in uninterrupted and undivided continuity from its base in the cell body to its peripheral tip". Clear enough one would think, but alas, the data are far less so. The evidence amounts to no more than the approximate constancy of tubule number in cross sections of six rat motor axons taken before and after bifurcations — a result that could obviously have arisen in several ways. Tubular continuity was presumably chosen as the explanation because it was consistent with the prevailing view of axonal dynamics. Tubules were believed to be synthesised at the soma and pushed out into the process; they were the continuous rails on which the fast transport ran. The whole story made such a neat package that it would have been churlish to worry about such corollaries as that the tubules in many parts of the mature nervous system would then be metres long. Best not to think of the recurrent laryngeal nerve of the giraffe.

Questions of continuity and point of origin also exist, although in a less extreme form, in non-neuronal cells. In fibroblasts, microtubules wander within the cytoplasm and can be seen by immunofluorescence as fine threads in tangled skeins. The method is sensitive enough to detect single tubules (Osborn *et al. J. Cell Biol.* **77**, R27; 1978) but cannot resolve those in bundles. In consequence it is impossible to say in most preparations where the tubules begin and end. In 1976, however, three laboratories described a way to cut this Gordian knot. The tubules are depolymerised with colchicine or other antimitotic agent, the drug is washed out, and the cells fixed as the tubules begin to grow back again and then stained with antitubulin. When this is done the reforming tubules are first found in discrete star-like bodies in the cytoplasm, usually close to the nucleus (all of this applies to interphase cells; mitosis is different). The tubules lengthen from these centres until eventually the original network is regained. There is usually one, sometimes two, of these centres in a cell and it seemed most reasonable to suggest that they were the centrioles or cytocentres which have sometimes been seen by electron microscopy within arrays of microtubules in interphase cells. The implication was then that in such cells all tubules lead to the cytocentre which serves as a nucleation point for their growth. This was analogous to the role of the nuclear assembly point envisaged for the nerve cell.

The picture at this time was simple and satisfying. There were one or two structures in a fibroblast, epithelial cell or neurone which are responsible for the initiation and subsequent growth of all the microtubules in that cell. A simple picture, satisfying — and shortlived. A few months ago in *Cell* (**16**, 239; 1979) Spiegelman and colleagues showed that a minor variation in the staining procedure can produce not 1 or 2, but 5 to 10 centres in the average fibroblast, all close to the nucleus and each with 10–30 radiating microtubules. The main change in procedure was a previous extraction with non-ionic detergent and the new result was attributed to the loss of background staining — the new centres emerging from the background like stars at dusk, so to speak. Even worse, the same approach when used on human fibroblasts or epithelial cells showed one or two major centres together with many single points so small that they seemed little more than individual tubules growing in the cytoplasm. There are a number of imponderable factors, as always. Is it possible that the preparation of cytoskeletons might disrupt the organising centres and scatter the newly growing pieces through the gutted cell? Or, to go back a step, how do we know that the recovery from antimitotic agents will follow the same course as growth in a healthy cell? Within the limitations of the method, however, the picture obtained by immunofluorescence is of multiple nucleating centres, possibly of several distinct types.

Back at the nerve cell, a cultured neuroblastoma when treated by the above procedure shows a single organising centre at the base of its one or two neurites (Spiegelman *et al. op. cit*). Dividing neuroblastomas look more like a fibroblast in that they have an average of 12 smaller sites distributed around the nucleus. Obviously as the cell 'differentiates', the multiple centres coalesce to a single one and from a timed series of specimens Spiegelman *et al.* show that this occurs, on average, before the neurite grows out. The intriguing possibility is thereby raised that this coalescence in some way instigates neurite outgrowth. At any event, the tubules in this study are still firmly anchored to organising centres, small or large, in the soma.

The hint that even this tenet might be on shaky ground existed in an ultrastructural analysis of crayfish nerve (*J. Neurocytol.* **3**, 73; 1974). Nadelhaft found that sections of the same axon at different points along its length could show a significant variation in microbutule number. His polite, but firm conclusion was that the hypothesis of microtubular continuity could not be universally valid. A conclusion that received a thumping validation in the July issue of the *Journal of Cell Biology* (**82**, 278; 1979). Here Chalfie and Thomson present a serial analysis of certain axons in the world's most photographed worm. These axons are notable for their distinct tubules which are larger than tubules elsewhere in the animal and very highly ordered. Serial sections show major fluctuations in tubule number along the length of these axons and frequent terminations. The tubules are in short lengths, between 6 and 27 μm, distributed in staggered arrays along the axon. Even more interesting is the observation that the two ends of each tubule are not the same. The distal end, furthest from the cell body, terminates in a cloud of light staining that is always right up against the plasma membrane. The proximal end can be anywhere in the cytoplasm but is characterised by central density in the tubule. Assuming that these features are not freaks of these specialised axons — and breaks can be found in other tubules in the animal — the Weiss and Mayr picture of continuity is roundly wrong. And the question of how microtubules grow, and from where, in neurones as in other cells, is back to the starting point. Perhaps the rabid reductionists are right and we will have to wait until the analysis of tubulin polymerisation *in vitro*, under controlled conditions and with defined components, provides the answer. There have been many such studies and they have revealed a rich and multifarious set of phenomena. It is true that they have yet to point to a single mechanism, but that is another story. □

Conformational flexibility in protein molecules

from Robert Huber

IN describing protein molecules the term flexibility is used with quite different meanings. A precise definition for a particular protein molecule would require the determination of the number, energy and geometry of the various stable conformational states the molecule might have, the kinetic parameters of interconversion and the thermal motion of all the atoms in each conformer: a considerable task, requiring a great variety of experimental techniques, if feasible at all. Several rather different experimental approaches have provided evidence that protein molecules are indeed flexible: deuterium–hydrogen exchange under non-denaturing conditions[1], fluorescence quenching of internal tryptophan residues by oxygen diffusing into the protein molecule[2], ESR, NMR, and fluorescence depolarisation. These last spectroscopic techniques allow one to determine the mobility as a function of temperature of certain residues whose spectroscopic signal can be identified. The power of these methods is clearly demonstrated by recent experiments, using NMR techniques, which show that the aromatic rings of tyrosyl and phenylalanyl residues in pancreatic trypsin inhibitor (PTI) flip[3-5]. Model calculations show that aromatic ring flipping is a consequence of substantial breathing motions of the protein, which include movement of the polypeptide backbone[6, 7]. The mobility of tryptophanyl residues has been probed, using very short and intense light pulses to measure fluorescence depolarisation[8]. Motions in the picosecond time range are found, but the degree of flexibility is different for different protein species, some being rather rigid, some soft. Recent molecular dynamics calculations on PTI[9] show structural fluctuations in the picosecond range of a size in rough agreement with the observed crystallographic temperature factor[10] and promise to provide the theoretical background to motions in proteins. However, the computational problems are enormous and, so far, allow the analysis of a small protein molecule such as PTI for a few picoseconds only. This makes extrapolation to equilibrium properties and comparison with the time-averaged crystal structures problematic, as does the neglect of solvent effects in calculations performed to date. More refined dynamics calculations are currently being pursued.

Protein crystallography as a means to gain information about flexibility is unique in providing us with an overall view of the molecule in contrast to the spectroscopic techniques which focus on a particular label. However, there are a number of theoretical and experimental problems. As the physical diffraction process is instantaneous compared with lattice vibrations, the 'temperature' factor determined crystallographically does not differentiate between thermal motion and static disorder. Static disorder may have components from conformational micro-heterogeneity of the protein molecules (substates or microscopic states) and from lattice defects. The interesting parameters, thermal motion and substates are difficult to determine accurately and still more difficult to separate from one another. The experimental problem has been partly overcome since the development of techniques for refinement of protein crystal structures, some five years ago.

Protein structures were successfully refined[10-12] using principles borrowed from small molecule crystallography, extensively modified and adapted to the much larger problem[13]. From these studies it was obvious that the 'temperature' factors of individual atoms were important variables for the correct description of the protein structure. However, the values were regarded with some suspicion, as they changed from atom to atom in a rather erratic way due to the limited resolution of the diffraction data. But, when the 'temperature' factors were averaged for rigid groups and smoothed along the main and side chains, physically reasonable features were obvious: 'temperature' factors increased in external polypeptide loops and external side chains were more mobile than internal ones.

Several examples of protein crystal structures are now known where disorder (either dynamic or static) is a dominating aspect: antibody molecules [14, 15], trypsinogen [16], citrate synthase[17], tobacco mosaic virus protein[18, 19] and tomato bushy stunt virus[20]. In these molecules substantial parts show no significant electron density indicating disorder in the crystalline state. In some of the molecular species rigid states are known with different functions, providing evidence for the functional significance of large scale disorder[21]. Except in the case of TMV protein, where NMR experiments have demonstrated increased thermal mobility of the disordered segments[22], it is unclear which type of disorder (conformational heterogeneity or thermal motion) prevails in these examples. Lattice defects involving the molecule as a whole are excluded, of course, as most parts of the molecules are well ordered.

Two reports in this issue of *Nature* are centred on the question of conformational disorder and its static and dynamic components determined by crystallographic methods in two different systems: lysozyme (Artymiuk *et al.* page 563) and myoglobin (Frauenfelder *et al.* page 558). Two different lysozyme species crystallising in different crystal forms have been carefully refined and atomic 'temperature' factors determined. When these were averaged for the main chain atoms of each residue a close correspondence between the two crystal structures was obvious, suggesting that the variation in 'temperature' factor along the chain is a molecular property and not seriously influenced by crystal packing. A detailed mathematical analysis indicates a rigid body translation and libration of the molecule as a whole, overlaid with additional flexibility of some external loops. Among these are the loops determining the substrate binding cleft in lysozyme. A positive correlation between ordered secondary structure and 'rigidity', and between shielding of amino acid side chains and their 'mobility' is obvious. The slightly enhanced 'mobility' of the substrate binding area is intriguing, in particular, if it were to be found that these segments 'rigidify' on substrate binding; one wonders why nature utilises such small effects, having in mind the drastic segmental flexibility in the examples discussed before. Artymiuk *et al.* do not and cannot dissect the 'temperature' factors observed into their static and dynamic contributions. This problem is the main object of the paper by Frauenfelder *et al.* who analysed and carefully refined

myoglobin crystals at various temperatures from 300 to 220 K, with the ultimate goal of differentiating static and dynamic disorder by their low temperature limit. As protein crystals contain solvent which may not be allowed to freeze, the temperature range that is covered is small as is the effect on the 'temperature' parameters determined.

The principal result of Frauenfelder *et al.*, that 'temperature' factors are increased in the peripheral parts of myoglobin and correlate with the secondary structural elements, agrees with the observations on lysozyme and other proteins discussed. The authors also follow and compare the variation of the 'temperature' factors with temperature for internal and peripheral atoms: they make the novel and interesting observation that internal atoms 'freeze' more than peripheral ones. This leads the authors to the view that conformational heterogeneity (substates) is a dominent type of disorder, at least for the outer parts of myoglobin. As the temperature range covered is small and the effects measured marginally above the level of significance, it would be highly desirable to back up these results by going to substantially lower temperatures, perhaps using the shock-freezing technique developed by Parak *et al.*[23, 24]. These authors had shown by Mössbauer absorption spectroscopy on myoglobin crystals that about half of the crystallographic 'temperature' factor is due to static disorder. Mössbauer absorption measurements are insensitive to static disorder as long as the equilibration between different conformers is slow compared with the life time of the excited Mössbauer nucleus. The question of whether a protein molecule is to be regarded as a vibrating aperiodic crystalline solid or a 'semiliquid' 'glass', characterised by a larger number of substates of similar energy, is a topic of lively discussion at present. Of course, there is clear evidence for alternative side chain conformations in protein crystals (see for instance Epp *et al.*[24] who observed conformational heterogeneity of an internal cysteine residue; or His E7 in erythrocruorin (Steigemann & Weber[25])). However, the uneasy feeling of a protein crystallographer about the 'semiliquid', 'glassy' protein picture comes from the fact that proteins are tightly packed[26], multiply linked and cross-linked molecules which may have problems finding efficient alternative packing except, of course, for residues and loops interacting with solvent. It would, perhaps, be appropriate to defer these arguments until it is possible to define more precisely the extent to which substates exist in a particular type of disorder. The differentiation between a single vibrating conformer and an assemblage of a huge number of closely related substates separated by low energy barriers and in rapid equilibration becomes a matter of semantics, except close to 0 K, a rather unphysiological temperature. □

Meteoroid fragmentation in the auroral zones

from David W. Hughes

SATELLITE measurements of the micrometeoroid dust particles in the Earth's vicinity have produced many interesting results in the last two decades. One of the more fascinating observations has come from experiment S 215 on the HEOS-2 spacecraft. Not only did this experiment measure the normal sporadic flux of these particles but it also found groups and swarms of micrometeoroids which had apparently been produced as lunar ejecta, and also as the debris from the electrostatic disruption of larger meteoroids.

H. Fechtig, E. Grün and G. Morfill of the Max-Planck-Institute for Nuclear Physics, Heidelberg, have produced a detailed analysis of these results in a recent edition of *Planetary and Space Science* (**27**, 511; 1979). We can dismiss the sporadic particles fairly quickly. They arrive randomly, (as expected) the number observed per unit time obeys Poisson statistics (as expected) and the flux is what one would expect from the zodiacal dust cloud, allowing for the enhancement produced by the gravitational field of the Earth.

A sizeable fraction of the observed particle events did not occur randomly, however, but came in correlated bursts, leaving the researchers with the problem of finding the sources of the particles responsible for these bursts. Two sources immediately sprang to mind — because there were two types of bursts. Swarm bursts lasted for less than 40 min and the time interval between consecutive particles was less than 10 min. This was taken to indicate that the source was comparatively close by. Group bursts had durations between 40 min and 13 h and the time interval between consecutive particles was less than 6.5 h. The source of the particles responsible for the group bursts was obviously further away.

A meteoroid impacting on the Moon will produce a crater. Ejecta from this crater will consist mainly of lunar crust material, some of it having a velocity in excess of the lunar escape velocity, while the velocity dispersion will also be of the order of the escape velocity. The HEOS-2 satellite is in an Earth orbit with a perigee of 10,000 km and an apogee of 244,000 km. The lunar ejecta has to travel about 384,000 km to reach the satellite, by which time it will have spread out in space as a result of the velocity dispersion. Reasonable assumptions show that it will take about 7 h to sweep past the spacecraft. The experiment was working between 7 February, 1972 and 2 August, 1974 and during this time 19 group bursts were seen, individual groups taking between 40 min and 13 h to pass the spacecraft. Fechtig, Grün and Morfill tried to correlate the observation times of the groups with the occurrence of seismic events on the Moon recorded by apparatus left behind by the Apollo astronauts. There were ten times more seismic events than group events. This fact is not too disheartening, however, for fast ejecta would leave the impact point at an angle of less than 10° to the surface, so only the lunar rim regions can provide ejecta detectable at the spacecraft.

The source suggested for the swarm bursts is the Earth's auroral zones. About 30% of the meteoroids in space with masses above 100 g have densities less than 1 g cm^{-3}, and these meteoroids are thought to be fragile, crumbly, loose conglomerate bodies made up of collections of individual particles in the micron and even submicron range. In interplanetary space meteoroids are positively charged with potentials in the range from +3 to +20 V. The main cause of this is the photoelectric effect. Solar quanta of sufficient energy (more than about 10 eV) may dislodge electrons from the surface layers of the meteoroid and sufficient numbers of these electrons escape the Coulombic back-attraction to leave the meteoroid positively charged. This charge is somewhat reduced by the capture of solar wind electrons and there are other much less dominant effects such as proton capture, secondary electron emission, sputtering and thermionic emission that can be neglected.

However when this meteoroid enters the ambient plasma of the Earth's magnetosphere at an altitude of about 60,000 km it quickly becomes negatively charged. The dominant charging process here is collection of electrons and protons from the Maxwellian plasma. Remember that the thermal electron and proton velocities are much greater than the meteoroid velocity. The majority of electrons and protons that hit the meteoroid stick to it. Also a meteoroid of radius greater than 10^{-5} cm can completely stop electrons of energies less than 10 keV and protons of energies less than 70 keV. S.P. Wyatt (*Planet. Space Sci.* **17**, 155; 1969) estimates that an iron, nickel or silicate meteoroid in sunlight at the Earth's orbit would be losing about 2.5×10^{10} electrons per second per cm^2 due to the photoelectric effect, so this has to be taken into account too.

Fechtig, Grün and Morfill consider two very dissimilar regions in the magnetosphere — first, the plasmasheet, a region outside the dipolar field regime. Here the electron number densities are

0028-0836/79/330539-01$01.00

©Macmillan Journals Ltd 1979

between 0.1 and 10 per cm^3 and the electron and proton energies are about 1 and 10 keV respectively. The second region is the inner magnetosphere, in the field line regime connected to the auroral zones. Here, especially during geomagnetically active times, the fluxes can be as high as 2×10^{10} particles cm^{-2} s^{-1} and the electrons have energies of about 40 keV. Although meteoroids seem to traverse the first region without harm, dust grains larger than 0.002 cm radius can be charged to very high potentials in the second region.

The authors estimate exactly how high this potential is from the HEOS-2 results. The internal disrupting stress, due to electrostatic repulsive forces, which acts on a meteoroid is proportional to the square of the ratio of surface potential to radius. For example, a surface charge of -500 V will break up a 100 μm diameter dust ball, a 1 μm diameter meteoroid made of compact stone or a 0.05 μm iron particle. The fragments of this electrostatic explosion have a dispersion velocity inversely proportional to the square of the radius. Now the swarms observed by HEOS-2 are made up of fragments of radii about 10^{-5} cm (mass about 10^{-14} g) and the maximum time taken for a swarm to pass the satellite was 90 min. An analysis of the fragment dispersion indicated that the mean surface potential required to break up the meteoroids was about -600 V and 90% of the meteoroids producing swarms broke up at potentials in the range between -300 and -960 V. It was obvious that in most cases the breakup only took place after the meteoroid had entered the inner dipolar field region of the magnetosphere, the region in which intense fluxes of energetic auroral electrons have been observed. A particle of radius r will charge up to -600 V in 0.13 r^{-1} s on entering the auroral zone.

The swarm data indicate that the primary particles are interplanetary in origin. From the area of the detector, the exposure time and the total number of swarms observed, the authors have estimated what percentage of the large interplanetary meteoroids incident on the Earth's atmosphere actually break up as they pass through the auroral zone. The swarm parent bodies have estimated masses in the range 10 g to 10^6 g. When the flux of swarm-producing meteoroids is compared with the flux of similar mass objects that produce lunar seismic events and fireballs visible to the Prairie Network of all-sky cameras, it is found that only between 1 and 10% of the incident bodies actually fragment into micron and submicron particles at auroral zone heights.

The parent bodies are from the same group that produce type III fireballs having low densities (<1 g cm^{-3}), low geocentric velocities (< 20 km s^{-1}) and orbits with semi-major axes around 1 AU. So in these few incidences the Earth's atmosphere is not hit by a single large meteoroid but is peppered by millions of submicron particles which will not produce meteors in the atmosphere but will simply be retarded and then drift slowly to the ground. Fragmentation takes place at a height of about 10 Earth radii. The average meteoroid observed was moving at around 8 km s^{-1} when it broke up and the fragments produced dispersed at about 1 km s^{-1}, thus peppering an area of about 10,000 km in diameter, of the same order of magnitude as the cross sectional area of Earth.

Fechtig, Grün and Morfill are continuing their research and expect to see similar effects in the vicinity of Jupiter which has a strong magnetosphere and a superfluity of moons. They have already designed a suitable dust experiment for inclusion in the Jupiter Orbiter Mission scientific package. □

Superfluid vortex waves

from P.V.E. McClintock

RADIO frequency vortex waves have been detected on quantised vortex lines in superfluid ^{4}He, according to a report by R.A. Ashton and W.I. Glaberson of Rutgers University in a recent issue of *Physical Review Letters* (**42**, 1062; 1979).

Vortex lines form in liquid ^{4}He if attempts are made to rotate a container of the liquid when it is below its superfluid transition temperature of 2.2 K. In this respect, as in many others, the superfluid behaves in a manner strikingly different from classical liquids. Whereas an ordinary liquid can rotate with its container much in the manner of a solid body (apart from acquiring a parabolic upper surface) superfluid helium is unable to rotate. In fact, for low enough angular velocities of the container, the superfluid apparently remains at rest relative to the fixed stars and does not rotate at all, no matter how long the experimenter rotates the container. If the container is speeded up, however, a single vortex line eventually appears; but the liquid still does not rotate as a whole. The vortex line is a microscopic quantal analogue of the eddy which is often seen as water runs out of a bath plug-hole; it is a line, parallel to the axis of rotation of the container, around which the liquid circulates with a tangential velocity which is inversely proportional to the distance from the axis, or core, of the vortex.

Speeding up the rotation of the container still further causes additional vortex lines to appear, all identical, because each one is singly quantised. At 1 rev s^{-1}, there are about 10^4 cm^{-2}. Since each line exists in the flow field of all the others, the whole array of lines rotates at the same rate as the container, thus to some extent simulating solid body rotation of the liquid as a whole and producing what appears to be a conventional parabolic surface (although, on the microscopic scale, one expects dimples where the cores of the lines touch the surface). Support for this general picture comes from a number of sources, but the most direct evidence is from the beautiful experiments performed at Berkeley by Packard and his co-workers, who have managed to take photographs of the vortices. One of their latest results (Yarmchuk, Gordon & Packard *Phys. Rev. Lett.* **43**, 214; 1979), reproduced in Fig. 1, provides a striking illustration of the structure of the rotating liquid.

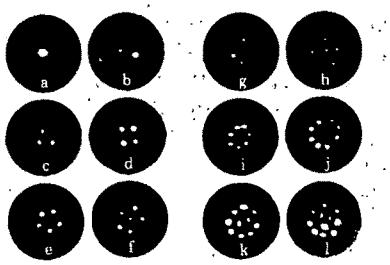

Fig. 1 Photographs of stable vortex arrays, looking along the axis of rotation. The angular velocities with which the 2 mm bucket was rotated varied from 0.3 rad s^{-1} to 0.86 rad s^{-1}.

The lines are potentially capable of supporting vortex waves: travelling helical deformations in which each element of line moves in a circle, though in the opposite sense to that of the vortex flow field. The phenomenon has been known for some time in relation to classical fluids, the first detailed study being due to Kelvin (*Phil. Mag.* **10**, 155; 1880). Early attempts to observe vortex waves in helium were based on torsional pendula, and were restricted to frequencies below 1 Hz; they yielded somewhat ambiguous results. More recently, however, it has been suggested that vortex waves of much higher frequency might be both excited and detected with the aid of negative ions.

Much of our knowledge of the quantised vortices has, in fact, been discovered through ion experiments. The negative 'ion' in liquid helium — in reality an electron confined within a 20 Å radius bubble — is easily trapped on a vortex line. Although it cannot escape in the direction perpendicular to the line, it readily slides along it under the influence of an electric field and, by measuring the velocity of the ion as a function of field, it has been possible to deduce information about the properties of the vortex itself. (The photographs in Fig. 1 were taken by shooting ions right off the top of the vortex lines to strike a detector placed above the liquid surface, thus revealing the position of each line.) Halley and Cheung suggested

(*Phys. Rev.* **168**, 209; 1968) that one way of exciting vortex waves might be to subject the line to a transverse oscillatory electric field while ions were travelling along it. This resonant excitation of vortex waves would have a corresponding effect on the motion of the ion. To achieve it, several conditions must be fulfilled. In particular, the ions should be moving along the line at the same speed as the propagation velocity of the vortex wave corresponding to the frequency of the applied electric field. Halley and Osermeier were subsequently able to calculate in detail (*J. Low Temperature Phys.* **26**, 877; 1977) how the velocity of the ion might be expected to vary with the d.c. electric field propelling them along the line. They predicted that there should be a kink in the velocity-field characteristic at a certain critical velocity, which depends on the frequency of the transverse oscillatory electric field.

Ashton and Glaberson have now performed this experiment, using a rotating ^{3}He cryostat in which the ^{4}He sample can be cooled to 0.3 K while being rotated at speeds of up to 10 rad s^{-1}. The transverse electric field was circularly polarised, so that resonant vortex wave production was expected to occur for only one polarisation for a given sense of cryostat rotation. Their experimental results are shown in Fig. 2. It is quite clear that the radiofrequency (RF) electric field has a considerable influence on the ionic velocity V, and that entirely different effects are obtained when the applied field is changed from a clockwise (CW) to a counterclockwise (CCW) sense relative to the rotation of the cryostat. An anomalous kink and plateau occurs in the velocity at about 3.6 m s^{-1}, in tolerable agreement with a theoretical prediction of 3 m s^{-1} for the RF frequency being used (10 MHz). This result can be regarded as a vindication of the principal conclusions of the Halley and Ostermeier theory. But the theory does not give a satisfactory account of the detailed shape of the velocity-field curve; nor is it able to explain the reduced values of V found in the CW rotation.

A good deal more work, both theoretical and experimental, will be required to sort out the details. Even on the basis of the present results, however, it seems clear that high frequency vortex waves really do occur in superfluid ^{4}He. □

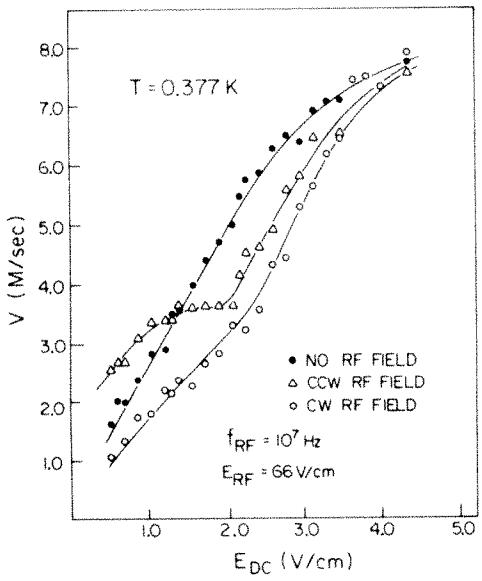

Fig. 2 Measurements of the ionic velocity V along a vortex line as a function of the longitudinal electric field E_{DC}: for zero applied radiofrequency (RF) field; and with the latter field polarised clockwise (CW) or counterclockwise (CCW) relative to the rotation of the experimental cell. The anomalous plateau and kink at about 3.6 m s^{-1} in the CCW curve is interpreted as evidence of a coupling of the ions to vortex waves.

Erratum

IN the article 'Hypercycles and the origins of life' in last week's *News and Views* (*Nature* **280**, 445; 1979), two lines were inadvertently transposed from the foot of the second column on page 445 to the middle of the second paragraph in the third column. Starting from the last line of column 2 the correct reading is "Then before long only one quasi-species would remain — GOD only, or THE only, if short words replicate faster." and in the middle of paragraph 2, column 3, the correct reading is "I_1 and I_2 are two RNA quasi-species. Both the + and − strands must be good replicators."

The cladistic debate continued

The critical view of the cladistic method of classification taken by L.B. Halstead in his report of a meeting on Vertebrate Palaeontology published in News and Views *some months ago (***276**, *759; 1978) and the rejoinder by a group of supporters of 'cladism' (***277**, *175; 1979) provoked a large correspondence, a selection of which is published below.*

There can be few disagreements on methodology in the recent history of biology which have been pursued with such passion by the protagonists, while leaving biologists not involved (in this case in systematics) so unmoved by, or even ignorant of, all the fuss. There is fruitful territory for psychologists here, but I would like to confine myself to the methodological rather than the theological aspects of the affair.

The fundamental tenet of cladism, is that in systematic biology the reconstruction of phylogeny is logically prior to the construction of a classification and that the latter is a redundant expression of the former. Unlike all other taxonomists, the cladists characterise phylogeny solely as the result of speciation or cladogeneses (the splitting of one species into two or more in evolution). They ignore the results of evolutionary change within evolving species (phyletic evolution or anagenesis). Furthermore in reconstructing phylogeny they allow division only by dichotomy: that is, speciation, according to them, is always the splitting of one species into two daughter species, sister species of one another. Primitive cladists held this as a dogma, which, with our current knowledge of evolutionary genetics, is patently absurd. Sophisticated advocates use it only as an operational principle. Nevertheless the rationale of the method depends on evolution by speciation which results in reproductive isolation between sexually reproducing organisms. Cladistic classification is therefore inapplicable to non-sexual organisms and will presumably never be used for microorganisms such as Protozoa, bacteria and viruses.

The recognition of sister species (or groups of higher rank) is by shared derived characters unique to the sister groups and thus presumed present in their (always hypothetical) unique common ancestral species. Shared primitive characters, those also present in collateral groups outside the pair, are ignored. Unfortunately if a large number of character states is considered, as it should be by any competent taxonomist, contradictions will arise due to convergently evolved characters mimicking true synapomorphies (shared derived ones). The method of resolving this difficulty destroys the whole rationale of the method of recognition of sister groups. The inconsistencies are resolved by using the principle of parsimony. By parsimony cladists mean that the sister-grouping which yields the smallest ('most parsimonious') number of contradictory characters compared with the number of apparent shared derived characters, *of those the cladist has studied,* is the correct one. This preposterous assumption could only be true if, first, an organism (be it lungfish, salmon or cow) could be analysed into a finite number of discrete characters, and, second, if a competent cladistic taxonomist could be reasonably sure that the tiny number of shared characters he can study in that organism has a similar ratio of true derived to convergent characters as does the class of all its characters.

Admittedly, traditional and also phenetic ('numerical') taxonomists use parsimony in an informal way, but they also use the criterion of predictability, perfectly described in the last century by John Stuart Mill, as an extrinsic criterion to test their classifications. Despite the fact that many cladists pay lip-service to the hypothetico-deductive method usually associated with the name of Sir Karl Popper, their only test of a cladogram appears to be a comparison, based on parsimony, with other contradictory cladograms. It is perhaps for this reason that a number of incompatible schemes for the mutual relationships of the major groups of fish-like vertebrates have been proposed by cladists, without any successful criterion within the system to choose between them.

At the risk of earning the opprobrium of your cladistic correspondents, I should like to end by pointing out that the problem I have touched on was well known to that very pre-Darwinian taxonomist Aristotle. In *de Partibus Animalium* (Book 1, paragraphs 2-4) he notes that a dichotomous classification based on a single character state will inevitably lead to an artificial classification (as it did recently when one eminent palaeontologist used it in the fundamental division of the Class Mammalia), but that the use of several character states leads to contradictions which cannot be resolved.

Cladism defended

THE contribution of L.B. Halstead to your journal was so misinformed about the assumptions and benefits of phylogenetic analysis that we are compelled to comment. A thorough presentation of phylogenetics ('cladistics') is inappropriate, but we do wish to make some remarks.

Phylogenetic methods are used to determine the most parsimonious arrangement of the patterns of character distribution among taxa (groups of organisms). These patterns are assumed to be the results of evolutionary processes and to reflect natural, monophyletic groups. The result of the analysis is a cladogram, a branching diagram with each branch justified by a character thought to be a unique evolutionary innovation. It should be noted that these diagrams are in fact hypotheses about relative recency of common ancestry among the taxa considered. 'Relationship' is thus defined by a genealogical criterion rather than such vague concepts as proportion of shared genes, as evidenced by supposed morphological similarity, or estimation of overall morphological similarity.

Dr Halstead's remarks about the phylogenetic system being designed such that fossils cannot be included is simply uninformed: many phylogeneticists have dealt with this issue, including one of us (E.O.W.) who published a phylogenetic analysis of fossil and Recent gar fishes.

Dr Halstead seems to be most interested in those evolutionary changes that 'allow' organisms to enter new 'adaptive zones', concepts widely used by grade-oriented systematists. He states, "the fact that many parallel changes can be related to adaptations to similar conditions, is more significant than listing trivial trademarks from which cladograms can be constructed." But, with some reflection, that statement yields a simple fact: parallel changes in evolution are not discernable, indeed are incomprehensible, without a genealogical hypothesis of relationship. Put simply, how can we know that similarity shared between two organisms is a parallelism without a phylogenetic tree which demonstrates that the character was not, in fact, found in the common ancestral species of the two taxa? This concept is so basic that we find it difficult to understand the misconceptions concerning it. Further, the "trivial trademarks" which mark monophyletic groups are often the very characters which are associated with new "adaptive zones" (for example, feathers of birds and mammary glands of mammals).

Dr Halstead states that if one could trace the ancestry of man back in time to a rhipidistian fish, the whole sequence of changes would, by definition, be a single monophyletic species. He adds that "most zoologists and palaeontologists" would surely use arbitrary divisions to partition that lineage. This misses another basic biological fact. The lineage is broken up, from the Devonian to the Recent. If this were not so, we would observe only one tetrapod species, *Homo sapiens*, and not the diversity of land vertebrates that we observe today. (Wiley (*Syst. Zool.*, 11-21, 1978) has shown that conclusions such as Halstead's stem from an artificial concept of classification.)

Since "the issue was summed up for many by R. Parrington's exasperated exclamation that according to the cladists a lungfish is more closely related to a cow than to a salmon," it is appropriate to end with a comment on that statement. It is not the cladist who 'makes' a lungfish more closely related to a cow than to a salmon any more than it is a cladist who 'makes' *Hyracotherium* more closely related to *Equus* than to Eocene condylarths. Evolutionary history as exemplified by genealogical descent with modification (a Darwinian concept) 'makes' it so. Lungfishes and cows are more closely related to each other than lungfishes are to salmons because lungfishes and cows share a common ancestor that is not shared with salmons. That this is somehow 'wrong' indicates a confusion on the part of critics about the meaning of genealogical relationship. If cladograms, with their clearly defined data and clearly stated hypotheses, "are difficult enough for experts in the field to comprehend fully," then we suggest that the shortcomings lie with the 'experts' and not with phylogenetic methods or their results.

As a non-participant in the scientific meeting of which Dr Halstead's report has stirred such sharp reactions in your columns, but as a previous exponent (*Classification and Biology*, Heinemann, 1970) of the principles excoriated by Halstead under the name of 'cladism', I would like to address four questions to him. First, would he agree that there is not, and probably cannot be, an objective measure of 'degree of similarity' between organisms in respect of phenotypic characters of the type studied by museum systematists, and in particular that the 'unit character' of the numerical taxonomists has proved to be undefinable? Second, would he accept that the most fundamental type of similarity or difference between organisms is that of their genotypes, as represented primarily by their nuclear DNA? Third, would he accept that we now have objective methods of measuring DNA similarity, either directly (by DNA hybridisation and similar techniques) or indirectly (by comparative protein studies) and that the range and reliability of data from these techniques is likely to increase? Fourth, if by such methods it could be shown that a lungfish was 'nearer' to a cow than to a salmon, would Dr Halstead then be prepared to accept the 'cladist' case in this instance. And if the answer to this question were "yes", would this alter his general attitude to phylogenetic classification in the sense proposed by Hennig (and myself)?

HALSTEAD states that the phylogenetic ideas illustrated in the "...cladograms presented by P. Janvier (University of Paris) on agnathans and B. Gardiner (Queen Elizabeth College, London) on choanichthyans ... were demolished within hours of their being proposed". I wish to reply to this statement, which is designed to dismiss cladistics in general and Dr Gardiner and myself in particular.

I proposed the following phylogeny based on cladistic methodology.

An objection was raised by Dr Halstead who did not agree with the proposed affinities of the Heterostraci, a group of poorly known fossil agnathans. He pointed out that heterostracans probably had paired nostrils and nasal sacs (diplorhiny) and were therefore related to gnathostomes and not to other agnathans which are monorhinous. This information is supposed to demolish my phylogeny and to support his own 'evolutionary tree' given below (with permission):

We agree that the diplorhinal condition is a primitive craniate character-state. Therefore, Halstead must believe that primitiveness is a criterion by which we recognise relationship. As a cladist I cannot accept this view.

If heterostracans did have paired nostrils (and not all palaeontologists accept this interpretation) then I have to recognise that monorhiny arose twice; in the hagfish and in cephalaspidomorphs. To counter this objection I could lean on detailed embryological and anatomical information to argue that the hagfish monorhiny had arisen independently of that seen in the lamprey. But this approach is both fruitless and unnecessary in the light of other information which I presented. Furthermore, basing one's case on whether heterostracans were monorhinal or diplorhinal is a particularly unfortunate tactic. Heterostracans are represented by thin bony shields and the interpretation of the soft anatomy is governed by the recent model we choose. This is amply demonstrated by the differing views of heterostracan morphology proposed by Stensiö[1] and Halstead[2] for instance.

Unless Halstead can provide derived character-states to show that heterostracans are more closely related to gnathostomes than to other agnathans then I submit that the 'demolition' amounts to no more than a dislike of my idea because it differs from his.

review article

Superheavy-element research

Günter Herrmann

Institut für Kernchemie, Universität Mainz, D-6500 Mainz, and Gesellschaft für Schwerionenforschung, D-6100 Darmstadt, FRG

The existence of an island of relatively stable elements beyond the present Periodic Table has been predicted by theoretical extrapolations of nuclear properties. During the past 12 years vigorous efforts have been made to discover these superheavy elements in nature and to produce them by nuclear reactions.

ALTHOUGH the existence of chemical elements much heavier than the known elements had already been considered more than two decades ago[1-3], these early studies did not receive much attention because for the heaviest known elements half lives in radioactive decay and production rates in nuclear reactions decrease steeply with increasing atomic number. Thus, there seemed no hope of proceeding to much heavier elements. In 1966, Myers and Swiatecki[4] pointed out, however, that the stabilising effects of proton and neutron shell closures should be strong enough for certain elements beyond the explored Periodic Table to ensure a local stability against spontaneous fission comparable to or even greater than that of uranium. Furthermore, Meldner and Röper[5] predicted that the next proton shell closure should occur at atomic number 114, a region not too far from the already synthesised heaviest elements.

The first detailed theoretical investigations of nuclear properties in this region[6-8] revealed the topology of an island of relatively stable nuclei (Fig. 1) as a consequence of shell closures at atomic number 114 and neutron number 184. The elements forming this island are called[3] superheavy elements. First estimates indicated half lives comparable to or even larger than the age of the Earth for nuclides in the centre of the island. Thus, superheavy elements could even exist in nature. The predicted long half lives encouraged many groups to search for such elements in terrestrial and extraterrestrial samples. The first negative results were published in 1969 by Thompson *et al.*[9,10] who looked for element 110; the first positive results were reported for element 114 in the same year by Flerov and Perelygin[11] but later work showed that the background induced by cosmic rays had been underestimated in the latter measurements. First attempts to synthesise superheavy elements in the laboratory by fusion of ^{248}Cm with ^{40}Ar projectiles had been reported a year earlier, again by Thompson *et al.*[10,12]. In contrast to the search in nature, attempts to produce such elements by nuclear reactions can presently be carried out at only a few places, namely with the heavy-ion accelerators at Berkeley (USA), Dubna (USSR) and Darmstadt (FRG).

Here the most recent results will be discussed. Detailed treatments of earlier and recent[16] work can be found elsewhere.

Nuclear and chemical properties

The decay mode ultimately terminating the Periodic Table will be prompt fission of the atomic nucleus. In terms of the well established liquid-drop model of the nucleus, the stability of heavy nuclei is a delicate balance between two forces, the short-range attractive nuclear force between nucleons and the long-range repulsive electrostatic force between protons. In the heaviest known nuclei the attractive force dominates slightly, leading to a fission barrier which keeps the nucleus together. However, an excitation energy of only about 6 MeV, small compared with the total potential energy of 1,800 MeV of such nuclei, is sufficient to overcome the fission barrier, as evidenced for example by the slow-neutron fission of ^{235}U and ^{239}Pu. Furthermore the nucleus may tunnel through the barrier from its ground state. This process, called spontaneous fission, becomes more and more likely towards the end of the present Periodic Table. Extrapolation of the liquid-drop model beyond the known elements shows that the fission barrier should vanish in the region around element 114 leading to prompt fission. Only the action of nuclear shell closures will overcome this trend by keeping the nuclei spherical and stiff against deformation, producing a fission barrier which is now entirely due to shell effects[17].

Most theoretical studies[17,18] agree that the next shell closures beyond the existing elements should occur at proton number $Z = 114$ and neutron number $N = 184$. Hence a maximum

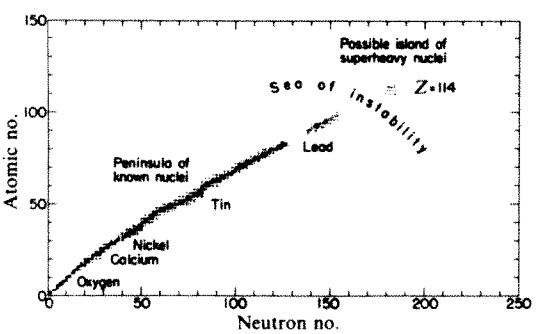

Fig. 1 Location of the island of superheavy elements relative to the peninsula of known nuclei. The heaviest points represent naturally occurring nuclei, the medium-weight points nuclei with half lives greater than 1 yr, and the lightest points nuclei with half lives less than 1 yr. The labelled elements correspond to nuclei with closed shells (from ref. 13).

© Macmillan Journals Ltd 1979

stability against spontaneous fission is expected for the isotope of element 114 with mass number $A = 298$. In addition to spontaneous fission, other decay modes must be considered—α decay, β^- decay and electron capture. Whereas the spontaneous fission half lives decrease from their peak value at $^{298}_{114}X^{184}$ rather uniformly in all directions, the α decay half lives show a rather continuous decrease with increasing atomic number so that this decay mode already dominates around element 114. Hence the longest overall half lives are shifted to lower atomic numbers. The other two modes, β^- decay and electron capture, keep the neutron-to-proton ratio of the most stable superheavy nuclei within a certain region. Figure 2 gives two examples of overall half lives calculated for superheavy nuclei with even proton and neutron numbers. The results[19] presented in Fig. 2*a* show an island with a maximum half life of 10^9 yr for $^{294}_{110}X^{184}$. A broad shore to the west is important since in the synthesis of superheavy elements by heavy-ion reactions, one approaches the island at this side. According to a more recent calculation[20] (Fig. 2*b*) the shape of the island remains nearly the same but the half lives decrease by orders of magnitude with a maximum value of 10^3 yr for $^{296}_{112}X^{184}$. Odd proton or neutron numbers should increase the half lives but the effect is expected to be small, about one order of magnitude[19]. A rather different and more unfavourable shape of the island was obtained in another calculation[21] yielding a steeper decrease at the west side due to the considerably lower fission barriers. For example, the 1 s contour line is already crossed at neutron number 180 for the elements 106–114. The longest half life, 10^5 yr, is calculated for $^{294}_{110}X^{184}$. In any discussion of half lives one should keep in mind the large uncertainties of about a factor of $10^{\pm 10}$ for spontaneous fission and $10^{\pm 3}$ for α and β decay half lives[13].

After evidence that elements around atomic number 126 exist in nature[22], the question of a proton shell at this number, in analogy to the well known neutron shell at $N = 126$, was reconsidered. Most calculations show[18,23,24] that the shell effect at proton number 126 should be small but stability in this region may be due to a strong neutron shell at neutron number 228.

When superheavy nuclei are formed in nuclear reactions, they carry a certain excitation energy and rotate with a certain angular momentum. Both these effects decrease the effective fission barrier. As theoretical calculations[25,26] indicate, the barrier will disappear at about 50 MeV excitation energy and 30 units of angular momentum.

In addition to the half lives for different decay modes, the energy released in these processes is of interest since it forms the basis for specific and sensitive detection techniques. The average total kinetic energy of fragments formed in spontaneous fission of superheavy elements (200–230 MeV) and the number of neutrons being evaporated from the fragments (about 10) should exceed[27,28] the corresponding values for any long-lived lighter nucleus. Hence fission events with high total kinetic energy and high neutron multiplicity should constitute a characteristic fingerprint for superheavy elements. Recent experimental data on fission of heavy nuclei indicate that the kinetic energy may even be higher, about 270 MeV, but the neutron multiplicity may be lower, about five neutrons per fission[29]. Calculated α-decay energies[19] are 6–10 MeV and lie within the range of other natural and artificial α emitters.

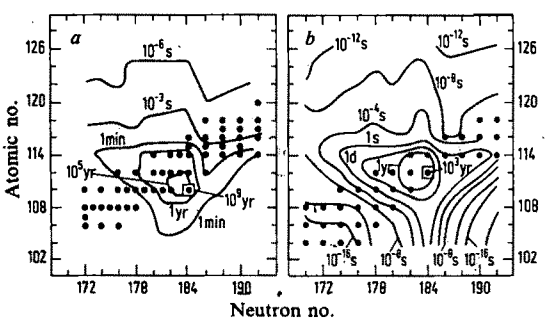

Fig. 2 Calculated half lives for superheavy nuclei shown as contours of constant overall half life plotted versus proton and neutron number. The points indicate nuclei calculated to be stable against β decay and electron capture: *a* is from ref. 19; *b* from ref. 20.

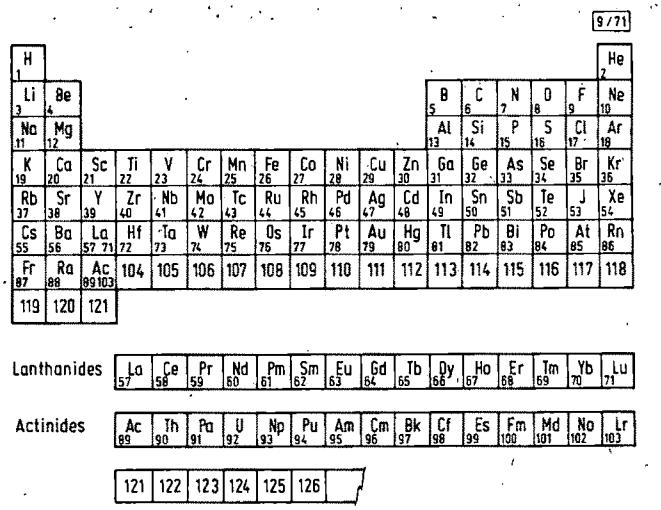

Fig. 3 Continuation of the Periodic Table of the elements into the region of superheavy elements according to quantum-mechanical calculations of their ground-state electronic structures.

The chemistry of superheavy elements was discussed[30,31] on the basis of their position in the Periodic Table and the systematic trends of chemical properties within the Table. Calculations of their ground state electronic structure[30,31] with the usual quantum-mechanical methods support a continuation of the Periodic Table as shown in Fig. 3. Accordingly, element 110 is expected to be a homologue of platinum, element 112 a homologue of mercury, and element 114 a homologue of lead. Element 126 should belong to a group of super-actinide elements in which the inner 6f and 5g electron shells are filled, and may thus behave like plutonium. The predicted high volatility of several superheavy elements[30–33] is interesting and may be enhanced by relativistic effects so that elements 112 and 114 might be expected to be volatile liquids or even gases as a consequence of relativistic stabilisation of the closed $7s^2$ electron shell in element 112 and a relativistic splitting between the $p_{1/2}$ and $p_{3/2}$ energies giving the filled $p^2_{1/2}$ orbital in element 114 the character of a closed electron shell[33]. Such predictions of chemical behaviour are relevant for the selection of natural samples in a search for superheavy elements and form the basis of chemical separation schemes applied in their isolation from such samples and from irradiated targets[31,32,34,35].

Atomic binding energies for inner-shell electrons, and hence transition energies of characteristic K- and L-series X rays have also been calculated with high accuracy[36] together with X ray transition rates[37]. Observation of a series of such characteristic X rays with the predicted energies and relative intensities in a sample would be considered as strong evidence for the presence of superheavy elements. General criteria for the discovery of new elements have recently been proposed[38].

The search in nature

If superheavy elements exist in nature they were probably produced in supernovae by a sequence of neutron captures and β^--decay processes, the latter increasing the atomic number stepwise. It is still debatable whether this *r*-process proceeds into the region of superheavy elements since it has to pass through a region of nuclei having a low fission barrier. After a neutron is captured in such a nucleus, the excitation energy gained from the binding of the neutron may exceed the fission barrier so that prompt fission will occur. Precise treatments of the *r*-process in the very heavy element region are hampered by

the comparable magnitudes of neutron binding energies and fission barriers and by the need to extrapolate over a large, unexplored region. Most of the recent studies consider the production of superheavy elements in the *r*-process to be unlikely[39–41].

The large uncertainties in the predicted half lives as well as the open question of production in nucleogenesis have not discouraged experimentalists from examining hundreds of samples for superheavy elements, including lead from old cathedrals, manganese nodules from the ocean floor, water from hot springs, meteorites, and samples from the lunar surface. Extremely sensitive techniques were developed for such studies[42], most of them being based on the direct or indirect detection of fission events. In counting untreated natural samples detection limits of 10^{-12}–10^{-14} g of superheavy elements per g of sample can be achieved for superheavy nuclei of 10^9 yr half life. The most common methods are counting of fission fragment tracks produced by radiation damage in glass, mica or plastics, and counting of neutrons emitted in the fission process. The sensitivity of such methods can be increased by chemical enrichment and mass separation. In an extreme case[43] samples collected during the industrial processing of 10^3–10^4 tons of lead were further concentrated by chemical and mass separation, and a detection limit of 10^{-19}–10^{-23} g per g was estimated for element 114.

Most of these searches produced negative results, but there are some observations which deserve attention and we report here on three: the hot spring water from the Cheleken peninsula, the Allende meteorite, and the Madagascan monazite.

In the hot springs from the Cheleken peninsula in the Caspian Sea a spontaneously fissioning activity was observed after passing about 2,000 m^3 of water through 850 kg of an anion exchange resin[44]. This particular spring water is known to be rich in volatile elements and is thought to collect material escaping from large depth in the Earth's mantle. Part of the resin was eluted with water and different acids followed by precipitation steps in the eluates. The samples were inspected with neutron-multiplicity counters which record the number of neutrons emitted in time coincidence. These neutrons are traced back to spontaneous fission events in the sample. The rates, about 0.5 fissions per day for a 9-kg sample of the resin and 5 fissions per day for the precipitates isolated from 170 kg of the resin, are much higher than what has been reported previously for any other sample inspected in low-background conditions. This allowed measurements of the neutron multiplicities with good statistics. Figure 4 compares the multiplicity distribution obtained[44] by summing the data for the resin and precipitate samples with the known distributions for several heavy nuclides and with some hypothetical distributions. Evidently the measurements rule out ^{238}U but agree with heavy actinides such as ^{252}Cf as a possible source of neutrons which may be present in the sample due to contamination in the laboratory or by fallout from nuclear weapons tests. From a small fraction of the combined precipitates, actinide elements were chemically isolated and inspected for α activity. Flerov *et al.*[44] argue that from these measurements, actinide nuclides except pure ^{252}Cf can be excluded as the source of the neutrons. Further experiments seem to be necessary in order to identify the spontaneous fission activity in the Cheleken hot spring waters.

Evidence for now-extinct superheavy elements in a certain class of primitive meteorites was presented by Anders *et al.*[45,46]. These carbonaceous chondrites contain xenon fractions with an excess of neutron-rich xenon isotopes. Such isotopes could stem from spontaneous or neutron-induced fission but the $^{136}Xe/^{132}Xe$ ratio observed is much larger than can be accounted for by any known fission reaction. The concentration of this fission-like xenon in different meteorites was observed to be correlated with the concentration of volatile elements such as thallium, bismuth and indium[45,46]. Fission xenon plus volatile elements were found to be strongly enriched in a mineral fraction comprising less than 1% of the meteorite and consisting of carbon, chromite, spinel and an ill-defined mineral, probably a sulphide[47,48]. From the parallelism in the condensation history of the fission-like xenon and of volatile elements as inferred from such data, it was concluded that the neutron-rich xenon isotopes stem from spontaneous fission of a volatile superheavy element, most likely from element 115, eka-bismuth, but elements 114 and 113 are other possible candidates[48]. Alternative explanations have been proposed mainly because the anomalous xenon fractions are also enriched in neutron-deficient isotopes[49,50] and similar enrichments both of neutron-excess and neutron-deficient isotopes are also found for other elements[51]. It has also been pointed out[52] that the predicted yields of xenon isotopes in spontaneous fission of superheavy nuclei would not fit the observed isotopic ratios. Whereas Anders *et al.* consider the progenitor of the fission-like xenon to be extinct, the Dubna group has reported weak spontaneous fission activities, about one event per month and kilogram, in several meteorites including Allende[53–55]. An attempt is being made to concentrate the activity from Allende by evaporation–condensation techniques to determine its atomic number[56].

Unexpectedly, evidence for element 126 and possibly 124 and 127 in nature was reported in 1976 by Gentry *et al.*[22] who examined small monazite inclusions surrounded by giant haloes in Madagascan biotite. Radioactive haloes[57] are spherical zones of discolouration of the host mineral caused by radiation damage due to α particles emitted from the central inclusion. Cuts through such haloes show a circular ring structure corresponding to the ranges in the host mineral of the α particles from different members of the radioactive decay series descending from uranium and thorium deposited in the inclusion. In the giant haloes, however, the ranges correspond to α-particle energies around 14 MeV which are much higher than the energies of any known natural α-particle emitter but agree with predicted α-particle energies in the region of element 126. By bombarding the inclusions with a sharply collimated proton beam, characteristic X rays of the elements contained in the inclusions were excited and small peaks were seen at the expected positions of the $L\alpha_1$ X rays of elements 126, 124 and 127. The concentrations for these elements as estimated from the peak intensities were surprisingly high, about 10–100 p.p.m. However, the strongest peak attributed to element 126 could be accounted for by a nuclear γ ray from the $^{140}Ce(p, n)^{140}Pr$ reaction already occurring at the proton energy chosen[58], and other peaks could be assigned to K X rays of ordinary elements such as antimony and tellurium[59]. The X ray spectra of the inclusions were remeasured[60,61] with a different technique using a tunable monochromatic X-ray source for excitation, thus circumventing the interference by proton-induced nuclear reactions and by excitation of the mentioned ordinary elements

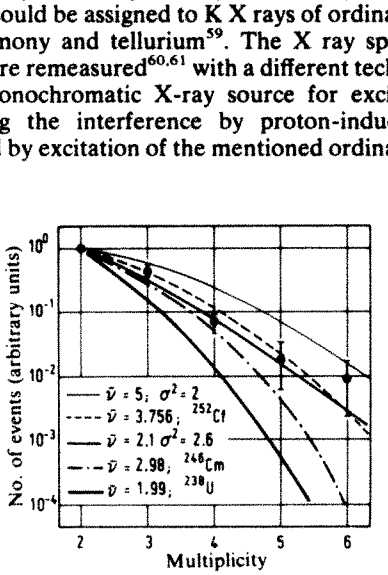

Fig. 4 Spontaneously fissioning activity in hot spring water from the Cheleken peninsula. Multiplicity distribution of fission neutrons emitted from samples obtained by ion-exchange and precipitation methods (●) compared with the measured multiplicity distribution for various actinide nuclides and with calculated distributions. The inset gives the corresponding values of the average number $\bar{\nu}$ of neutrons per fission and of its variance σ^2 (from ref. 44).

because of the differences in absorption edges. No evidence for superheavy element $L\alpha_1$ X rays was found[61] at a concentration level about a factor of 100 below that previously reported[22]. Although Gentry[62] agrees that the evidence was not confirmed, other members of the original group[22] argue that problems in reproducing the earlier measurements are due to spatial inhomogeneities of the superheavy element distributions in the samples and to their volatility[63,64]. Attempts to enrich superheavy elements from bulk monazites of the same origin by mass separation[65] and chemical separation[66] have failed. Surprisingly, evidence for high-energy α rays necessary to understand the giant haloes has recently been reported for the Madagascan monazite[67] in contrast with other negative findings[68,69]. There seems to be no convincing evidence that giant haloes have anything to do with superheavy elements but none of the alternative explanations[62] for the origin of these haloes has generally been accepted.

Searches at accelerators

Heavy-ion reactions seem to be the only practical way of producing superheavy elements in the laboratory. As shown in Fig. 1, one would jump in one step from the peninsula of known nuclei to the superheavy island. In heavy-ion reactions[70], three principal mechanisms play a part. The first is an exchange of a few nucleons between the two colliding nuclei in a rather distant collision and is called quasi-elastic transfer. The other two processes occurring in closer collisions are outlined[71] in Fig. 5 with their characteristic time scales in units of 10^{-21} s. The upper branch illustrates complete fusion[72] of the reacting nuclei to form a nearly spherical, excited compound nucleus which gains its energy from the fact that generally more kinetic energy is required to overcome the mutual electrostatic repulsion between the interacting nuclei than is consumed in the fusion process. The excitation energy is large enough to evaporate from the compound nucleus several neutrons, protons, or α particles followed by emission of γ rays to reach the ground state of the final evaporation residues which have the same or somewhat lower atomic number than the compound nucleus. For heavy compound nuclei, fission into two fragments of comparable size competes with evaporation and dominates for the heaviest known nuclei. Fusion to a compound nucleus occurs preferentially in reactions with relatively light projectiles such as carbon, oxygen or argon.

The third process[73–75] is shown by the lower branch of Fig. 5. The two interacting nuclei stick together for a very short time, about 10^{-21} s, forming a composite system which separates again into two nuclei roughly identical with the interacting nuclei in the entrance channel. In spite of the short contact time, the kinetic energy of the projectile can be completely transformed into internal excitation and into rotation, and hence the process is called strongly damped or deep inelastic collision. During such a reaction a substantial number of protons and neutrons can be transferred between the interacting nuclei. The reaction

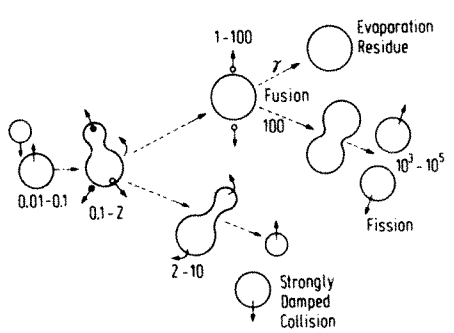

Fig. 5 Interactions between heavy nuclei leading to fusion into a compound nucleus (upper branch) and to damped collisions via a composite system (lower branch) with characteristic times in units of 10^{-21} s (after Brix[71]).

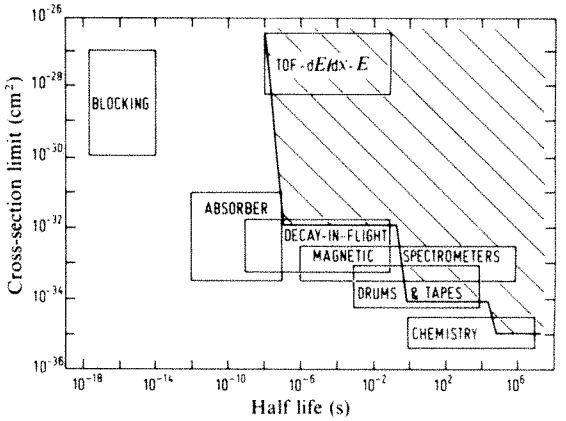

Fig. 6 Half-life region covered by various techniques applied to or applicable to the search for superheavy elements at accelerators, and upper limits for production cross-sections achievable with these techniques (from ref. 78).

products de-excite by emission of neutrons, protons, and γ rays and, in heavy systems, by fission. Although this novel type of nuclear reaction was discovered two decades ago[76,77] it has received widespread interest only recently, after its important role in the interaction of heavy nuclei was recognised.

A wide variety of techniques has been developed and applied in searches for superheavy elements at accelerators[78]. Figure 6 shows that techniques applicable to very short-lived nuclides are in general less sensitive than those suitable for longer half lives. Chemical methods combined with fission-fragment detection reach down to production cross-sections of 10^{-36} cm^2 corresponding to production rates of about one superheavy atom in 10^{12} nuclear collisions, but require half lives of at least a few seconds. Gas-jet systems for rapid transport of the activity from the production site to the detector system extend the half life range to shorter half lives by about one order of magnitude. Mechanical transport systems like tapes, drums or disks which are applicable to species of 10^{-3} s half life are even faster. The region down to 10^{-6} s is the domain of instruments based on the deflection of reaction products in magnetic and electric fields. Measurements of the time-of-flight (TOF) for a given distance and of the specific energy loss plus total energy ($dE/dx - E$) are widely used in studying heavy-ion reactions to obtain mass and atomic number distributions of the reaction products. When applied to superheavy nuclides they permit the detection of species with half lives down to 10^{-8} s. Detection of fission fragments emitted in flight from a superheavy nucleus passing a gas-filled tube extends the half life range which can be covered by one order of magnitude. By stopping superheavy atoms in a metal foil and observing their fission fragments in a direction perpendicular to the original flight path, nuclei with half lives down to 10^{-12} s can be detected. The extreme region, 10^{-14}–10^{-18} s, becomes accessible by the blocking technique in which the reaction products are produced in a single crystal and the probability of escape of their fission fragments is measured for different crystallographic directions, indicating the distance traversed by the fissioning species in the crystal; thus the half life can be deduced since the velocity of the recoiling nucleus is known.

Because most of the heaviest synthetic elements were produced by heavy-ion fusion reactions it was quite natural to use fusion in attempts to synthesise superheavy elements. The problem with this approach lies in the extreme neutron excess of the most stable nuclei in the centre of the island which makes it impossible to reach those nuclei by any realistic fusion reaction. For example the first attempt[10,12] to produce element 114

$$^{248}_{96}Cm^{152} + ^{40}_{18}Ar^{22} \rightarrow ^{288}_{114}X^{174}$$

leads to a hypothetical compound nucleus with 174 neutrons only, which should further evaporate four neutrons due to its

excitation energy yielding the isotope $^{284}_{114}X^{170}$ far away from the $N = 184$ neutron shell. After detailed half life estimates for superheavy nuclei became available it seemed to be possible to overcome this problem by overshoot reactions, that is by producing nuclei beyond the region of highest stability but with rather high neutron number which should then decay by electron capture (EC) towards the centre of the island. To illustrate this a reaction is considered which has a crucial role in attempts to synthesise superheavy elements:

$$^{248}_{96}Cm^{152} + ^{48}_{20}Ca^{28} \rightarrow ^{296}_{116}X^{180}$$

After evaporation of four neutrons the following decay chain would be expected, with half lives generally increasing along the chain[19]:

$$^{292}116^{176} \xrightarrow{\alpha} ^{288}114^{174} \xrightarrow{EC} ^{288}113^{175} \xrightarrow{EC} ^{288}112^{176}$$

the latter nuclide should decay by spontaneous fission with a half life of ~1 h.

Table 1 surveys fusion reactions which have attempted to produce superheavy elements. The upper limit of the production cross-section is listed together with the half life range covered and an indication of whether chemical separation methods were applied. Table 1 re-emphasises the dilemma of fusion reactions: in the vicinity of element 114 the achievable neutron numbers are far below 184 whereas this closed neutron shell can only be reached with atomic numbers as high as 122. A more detailed analysis of these reactions in terms of excitation energy of the compound nuclei and survival against fission in the neutron evaporation chain can be found in a recent review[90].

Among the systems listed in Table 1 the reaction between ^{248}Cm and ^{48}Ca has been studied the most intensively since this reaction provides the closest approach to the island if both the proton and neutron numbers are considered. Experiments with this reaction are difficult, however, since neither the target, the artificial nuclide ^{248}Cm with 3.6×10^5 yr half life, nor the projectile ^{48}Ca, which has to be enriched from its low natural abundance of 0.19%, is generally available. The results reported so far for the ^{48}Ca-on-^{248}Cm reaction are summarised in Fig. 7 where the upper limits for production cross-sections are plotted against the half life range covered with a particular technique. A variety of techniques has been applied. The Dubna group[81] (D in Fig. 7) applied two different chemical separation methods and inspected the samples by spontaneous fission (SF) and α-particle counting (α). At Berkeley (BL) two different chemical procedures (chem) were used[91] and an experiment designed to detect extremely volatile elements during and after bombardment was performed (gas)[92]. Attempts were also made to detect short-lived species by counting without chemical treatment the catcher foils in which the reaction products recoiling out of the target were collected (foils)[91]. In further experiments, the recoil atoms were stopped in a gas and transported with a gas jet to a rotating-wheel counting system (VW)[93]. Finally spontaneous-fission decay in flight was searched for (dif)[93].

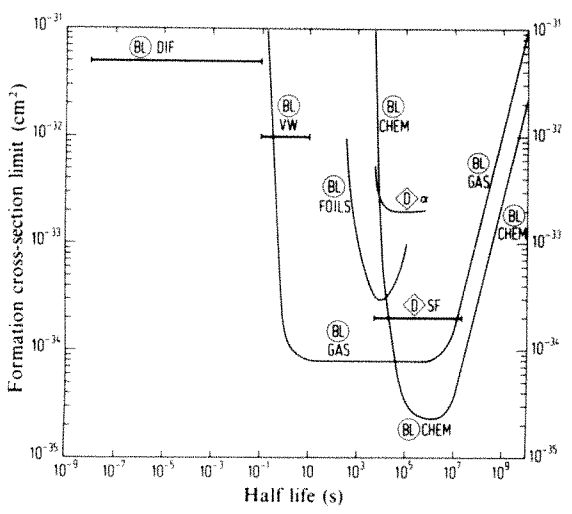

Fig. 7 Upper limits of the production cross-section for superheavy elements in the reaction of ^{248}Cu with ^{48}Ca versus the half-life range covered with different techniques. The data are from work of the Berkeley–Livermore group[91–93] (BL) and the Dubna group[81] (D); for details see text.

Table 1 Attempts to synthesise superheavy elements by complete fusion reactions

System*	Compound nucleus	Upper limit for production cross-section‡ (cm²)	Half life range covered	Ref.
$^{232}_{90}Th + ^{48}_{20}Ca$	$^{280}110^{170}$	3×10^{-35}	$\geq 3 \times 10^{-3}$ s	79

* If the projectile beam was not isotopically clean the mass number used here is in parentheses.

† Denotes studies in which chemical separation methods were applied at least in part of the measurements.

‡ Note that in calculating cross-section limits different authors use different assumptions about the width of the excitation function for the nuclear reaction involved; this introduces an uncertainty of about one order of magnitude[86].

Why these experiments have failed has been discussed in detail by Seaborg *et al.*[90]. The bombardments were carried out at an average energy exceeding the coulomb barrier by a factor of 1.09 resulting in some 40 MeV of excitation energy of the compound nucleus. Based on the measured production cross-section of the fusion product $^{254}_{102}$No in the ^{48}Ca + ^{208}Pb reaction, a fusion cross-section of at least 10^{-27} cm² was estimated for the ^{48}Ca–^{248}Cm system. Thus the reasons for negative results were sought in the evaporation chain. Using two sets of calculated fission barriers the overall survival probability was estimated. Whereas the optimistic set[19] predicts that 96% of the compound nuclei should arrive at $^{292}_{116}X$, the more pessimistic set[21] predicts less than 4×10^{-9}%, corresponding to a production cross-section of the order of 10^{-38} cm². One may attempt to increase the survival probability by lowering the bombarding energy in order to produce less excited compound nuclei. In theoretical studies[94,95] of fusion reactions it is pointed out, however, that the bombarding energy in the performed experiments was still too low[95] by 10–30 MeV since an extra push of energy is required to fuse two nuclei. A general consequence of this analysis[90] is that it

may indicate a steeper descent of the island on its west shore than found in calculations as shown by Fig. 2. If this is the case, to produce superheavy elements by complete fusion is apparently hopeless, a result which agrees with the numerous negative results listed in Table 1. Oganessian *et al.*[81] argue that either a low fusion cross-section or short half lives may explain the negative results with the $^{48}Ca + ^{248}Cm$ reaction.

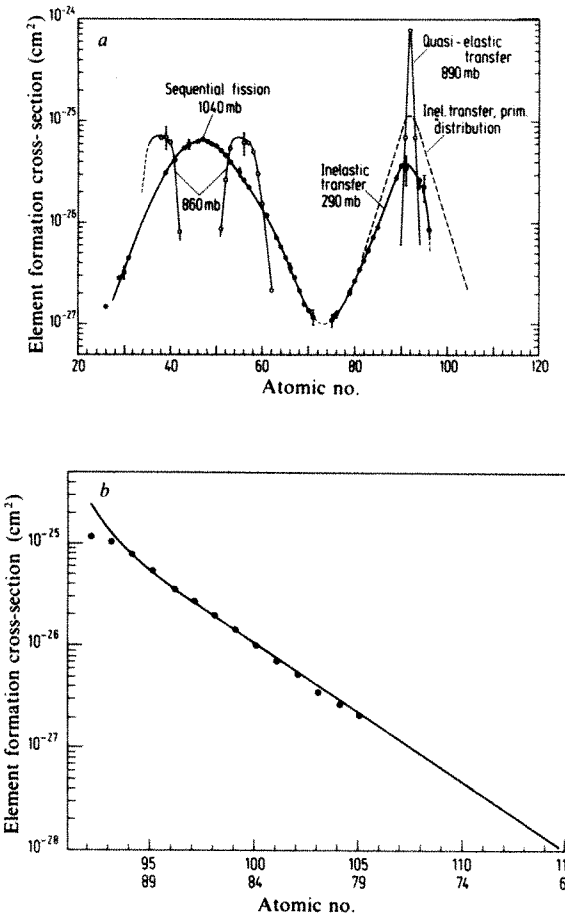

Fig. 8 *a*, Element formation cross-sections in the reaction of ^{238}U with ^{238}U as obtained by a radiochemical analysis of the reaction products produced in thick uranium targets bombarded with 7.5 MeV AMU^{-1} uranium ions (from ref. 102). *b*, Element formation cross-sections for complementary fragments in the $^{238}U + ^{238}U$ reaction deduced from experimental data as shown in *a* (●), compared with values calculated (solid line) using the diffusion model of damped collisions (after Riedel and Nörenberg[103]).

Are there any alternatives? A first hint in other directions seemed to be the observation of a 150-d spontaneously fissioning activity[96,97] produced with a cross-section of 10^{-33} cm^2 in bombardments of ^{238}U with ^{136}Xe and attributed to a superheavy element because of its chemical behaviour which was tested in a few bombardments. Flerov *et al.*[96,97] assumed that a fusion–fission process occurred but this is an unlikely mechanism for reactions between very heavy nuclei, as more recent studies have shown. Attempts to reproduce these findings, failed[85,98–100], however, in spite of an increase of the sensitivity by two orders of magnitude[99].

An alternative pathway to the superheavy elements was opened[101,102,35] by the first studies of the reaction between two colliding uranium nuclei carried out at the Darmstadt UNILAC accelerator when, for the first time, uranium beams with energies sufficient to overcome the interaction barrier even for uranium became available. These studies[101,102] demonstrated that the superheavy island might be reachable by exchange of nucleons in damped collisions. The evidence is still indirect and is based on the observation of complementary products. One of the colliding uranium nuclei increases its proton and neutron number at the expense of the other uranium nucleus

$$^{238}_{92}U^{146} + ^{238}_{92}U^{146} \rightarrow ^{298}_{114}X^{184} + ^{178}_{70}Yb^{108}$$

This implies, of course, that such damped collisions are binary reactions and that charged-particle evaporation plays only a minor part. There is strong evidence for these assumptions[73–75].

Figure 8*a* shows the element distribution in the reaction between two ^{238}U nuclei as obtained in radiochemical studies[102] by measuring a network of formation cross-sections for individual nuclides. The element yields peak at uranium in a narrow distribution due to quasi-elastic transfer. The underlying, broader distribution results from nucleon transfer in damped collisions. Reaction products from both types of reactions undergo fission as is evident from the broad distribution of fission products between element 30 and 70 and the steep decrease of the cross-sections beyond uranium due to increasing fissionability of transuranium nuclei. This decrease was followed over eight orders of magnitude up to fermium ($Z = 100$) whose element formation cross-section is 8×10^{-33} cm^2. Before fission occurs the element distributions both in the quasi-elastic and in the damped collisions should be symmetric around uranium for reasons already mentioned. The primary distribution originating from damped collisions can easily be reconstructed and is shown by the dashed curve in Fig. 8*a*. Extrapolation of this distribution to element 70 results in a cross-section of 10^{-28} cm^2 for the element 114–70 combination. A more sophisticated extrapolation is shown in Fig. 8*b* where the element cross-sections obtained experimentally are compared with values calculated [103] using a model which treats the nucleon transfer in damped collisions as a diffusion process[104]. The agreement between experimental and calculated cross-sections is very satisfying. For the element 114–70 combination again a production cross-section of 10^{-28} cm^2 is calculated.

But what fraction of element 114 may survive fission? It is an attractive feature of damped collisions that the reaction products are formed with very broad distributions in excitation energy and angular momentum, tailing to low values which are essential for survival. Counter experiments[101] and an analysis of production cross-sections of the highly fissionable transcurium nuclides[102] have shown that the excitation energies of fragments originating from the uranium-on-uranium reaction are unusually low if compared with other reactions between heavy nuclei. Calculations[103] with the diffusion model predict at 8.3 MeV AMU^{-1} bombarding energy production cross-sections of about 10^{-34} cm^2 for element 114 nuclei with <30 MeV excitation energy, an energy range for which the survival probability is estimated[25] to be >50% for the first neutron-evaporation step provided the neutron number is close to 184. It has been shown for damped collisions with light[75,105] and heavy[106] projectiles that the most probable neutron numbers for a given element split corresponds to a maximum mass difference between interacting and product nuclei with a minor correction for nuclear pairing energies. Applying this concept to the uranium-on-uranium reaction leads to $N = 180$ and $N = 182$ as the most probable neutron numbers for element 114 fragments. Taking all these estimates together one may expect production cross-sections of about 10^{-35} cm^2 for element 114. This corresponds, with the accessible beam intensities, to production rates of a few atoms per day or per week a rate just exceeding the detection limit of the most sensitive methods available at present.

Direct searches for superheavy elements in the uranium-on-uranium reaction have so far been negative. Looking for spontaneous fission events from reaction products implanted in a semiconductor detector gave an upper cross-section limit of 2×10^{-32} cm^2 for half lives between milliseconds and months[101]. With the gas-jet technique an upper limit of $1.5–3 \times 10^{-33}$ cm^2 has been reported for half lives between 1 and 10^5 s[85], and 10 and 10^3 s[107]. A more sensitive chemical experiment with a separation method based on volatilisation gave an upper limit of

10^{-35} cm^2 for half lives between several hours and one year, but further experiments using modified techniques are underway[108].

The use of heavier elements is obviously very attractive. Calculations with the diffusion model predict[103] an increase in the production cross-section for element 114 by two orders of magnitude when ^{248}Cm instead of uranium is bombarded with uranium projectiles. On the other hand the use of ^{244}Pu as projectile as proposed by Seaborg *et al.*[90] offers no advantages if compared with uranium[103]. Another factor of seven may be gained with a ^{249}Cf target but the gain may be illusory because of the limited availability of such exotic targets. Furthermore the estimated most probable neutron number moves away from the 184 neutron shell for targets heavier than ^{244}Pu.

Another mechanism for formation of superheavy elements has been suggested[109]. When fissile nuclei are used as target or projectile they may undergo fission under the influence of the other partner, and one of the fission fragments may fuse with the projectile to form a superheavy nucleus. Experiments[110] following this suggestion in which lead was bombarded with ^{136}Xe yielded negative results with an upper cross-section limit of 1.2×10^{-30} cm^2 for half lives between 10^{-12} and 10^4 s.

Outlook

There is no convincing evidence that superheavy elements have been discovered. On the contrary, the negative results produced by strong efforts in many laboratories during the past dozen years are discouraging. Yet, there is at least one natural source, the hot spring water from the Cheleken peninsula, which deserves attention, and similar springs may exist elsewhere. Also, reactions between very heavy nuclei have not yet been fully explored as a possible pathway to the superheavy elements in the laboratory. Whatever the final outcome, the intense exploration occasioned by the search for superheavy elements is bound to lead to a better understanding of the forces that terminate the Periodic Table at its upper end.

I thank G. Friedlander, H. Gäggeler, J. V. Kratz, W. Nörenberg, C. Riedel and N. Trautmann for discussions.

The rare Phanerozoic rock type boninite petrographically resembles Archaean basaltic komatiites and the range of boninite compositions overlaps that of basaltic komatiites. Quench amphibole and hydrous glass in the groundmass of boninites confirm earlier ideas that they may be the products of partial melting of peridotite in hydrous conditions, whereas basaltic komatiites have been assumed to result from fractionation of dry melts. Where field relationships are known, boninites are found either in ophiolites or a fore-arc tectonic environment.

BONINITES, first described in 1890 (ref. 1) in Cenozoic lavas from the Western Pacific, have chemical compositions similar in some respects to magnesian andesites. They bear a remarkable resemblance to basaltic komatiites which form a substantial component of Archaean vulcanism (Fig. 1). Rocks which we consider to be boninites, containing rapidly grown pyroxene and microphenocrysts of olivine and/or low-calcium pyroxene set in a glassy matrix are relatively widespread amongst ophiolitic basalts. This article offers new petrological information on these important rocks with implications for the origin of at least some ophiolites.

The use of the term boninite requires explanation. Kikuchi[1] described two rocks from Chichijima in the Bonin or Ogasawara group, Western Pacific. One contained phenocrysts of orthopyroxene (bronzite) and skeletal augite set in a dark glassy matrix "comparatively free of the palagonitic alteration product". The chemical analysis (analysis 1, Table 1) was of a "glassy portion" of the rock which we interpret as meaning close to the liquid composition. The other rock had phenocrysts of bronzite, augite and plagioclase feldspar in a groundmass of augite, plagioclase and glass (analysis 2). Petersen[2] introduced the name boninite and presented a third analysis of a soda-rich, probably altered rock (analysis 3) which he described as a feldspar-free, glass-rich variety of bronzite–andesite with olivine and augite.

Later, Tröger[3] gave analysis 1 as the type boninite and mentioned possible groundmass olivine as part of the mode. We concur with Tröger's choice and redefine boninite as follows: a highly magnesian but relatively siliceous, glassy rock containing one or more varieties of pyroxene, some or all of which have a morphology characteristic of rapid growth, accessory magnesiochromite and, commonly, minor amounts of olivine. Laths of amphibole or plagioclase microlites are rare.

Although boninites could be called high-magnesium andesites[4] their mineralogy, texture and high chromium and nickel contents differ so markedly from those of typical andesites that we consider the separate term justified.

Samples conforming to our definition of boninite were studied from the type locality, Chichijima in the Bonin islands[1,2,5,6] (Oligocene), the Dabi volcanics, Cape Vogel peninsula, eastern Papua[7–9] (?Oligocene), the uppermost Upper Pillow lavas of the Troodos massif[10,11] and Arakapas Fault belt[12], Cyprus (Cretaceous), the Agrilia Formation of the Othris Mountains, Central Greece[13] (Triassic) and from dredge haul 1403 at 12° N on the inner wall of the Mariana Trench[14,15] (Upper Eocene, unpublished data). Boninite has recently been recovered from a similar tectonic environment at 18° N in Hole 458 on Leg 60 of the IPOD drilling programme[16]. Palaeozoic rocks with similar

textures occur in the Betts Cove ophiolite[17] and within the Central Heathcote 'greenstone' belt, Victoria[18], but these contain augite and chromite as the only relict phases. Probable equivalents from Rambler, Newfoundland[19], and the Dundas Trough, Tasmania[20], have been completely recrystallised.

Basaltic komatiites with good textural and mineralogical preservation are rare; our analytical study involved specimens from the Belingwe greenstone belt Zimbabwe-Rhodesia[21,22], and was supplemented by data from equally fresh material in the Abitibi belt of northern Ontario[23,24]. Texturally, basaltic komatiite flows contain clinopyroxene, some or all with a morphology indicative of rapid growth; olivine, in the more magnesian lavas; and commonly groundmass plagioclase which varies from microlitic to intergranular. Pigeonite cores to augite are relatively rare and orthopyroxene is restricted to the cumulus zones of very thick flows.

Mineralogy

The compositional ranges of the primary minerals are given in Table 2; the complete analyses will be presented elsewhere. Olivine compositions in the boninites were found to vary from Fo_{93-83}, depending largely on crystal size. Phenocrysts (generally 1.0–10 mm long) found in the 'ultramafic lavas' of Cyprus[25,26] and Othris are Fo_{93-91}. Microphenocrysts (0.2–0.6 mm) form 5–10% of the mode in pseudomorph or unaltered form in almost all the other samples studied; the vast majority have compositions between Fo_{90} and Fo_{87}. Tiny skeletal olivines occur in the glassy matrix of several of the Cyprus boninites and have compositions between Fo_{88} and Fo_{83}. Some of the phenocrysts but few of the microphenocrysts are corroded and none shows a reaction relationship to calcium-poor pyroxene.

In basaltic komatiites, olivine (almost invariably pseudomorphed) typically occurs as microphenocrysts or skeletal grains 0.2–0.4 mm long. One rock from Belingwe, Zimbabwe-Rhodesia, has completely unaltered olivine microphenocrysts of composition Fo_{88} and abundant groundmass olivine, sometimes euhedral, with compositions as iron-rich as Fo_{82}. In a thick basaltic komatiite flow (19% MgO) from Munro Township cumulus olivine of comparable composition (Fo_{89-87}) was found[27]. Olivines in both the Belingwe komatiite and boninites generally have high nickel and calcium contents (>0.20%) but boninitic olivines have lower chromium content (<0.08%), suggesting that the order of crystallisation we observe petrographically in komatiites, olivine→chromite, is reversed in boninites.

Calcium-poor pyroxene occurs in all boninites except those from Othris, either as clinoenstatite (Cape Vogel, Mariana Trench) and orthopyroxene, or exclusively the latter. Phenocrysts (up to 3 mm) are present in most of the Cape Vogel rocks and in a few of the Mariana Trench and Bonin samples. Their Al_2O_3 contents are low, 0.1–1.1%, although they have very high Mg/(Mg+Fe) ratios (Fig. 2, open symbols). Microphenocrysts of orthopyroxene are common in the Cyprus rocks and have 'quench' overgrowths of augite. Groundmass orthopyroxene consists of laths intergrown with pigeonite and augite, or discrete cruciform shapes. Magnesian pigeonite has either nucleated on orthopyroxene grains of slightly higher Mg/(Mg+Fe) ratio or from the liquid. More often augite mantles orthopyroxene which may in turn be intergrown with clinoenstatite. Phenocrysts of calcic pyroxene are rare both in boninites and komatiites; their compositions lie close to $En_{52}Wo_{41}Fs_7$.

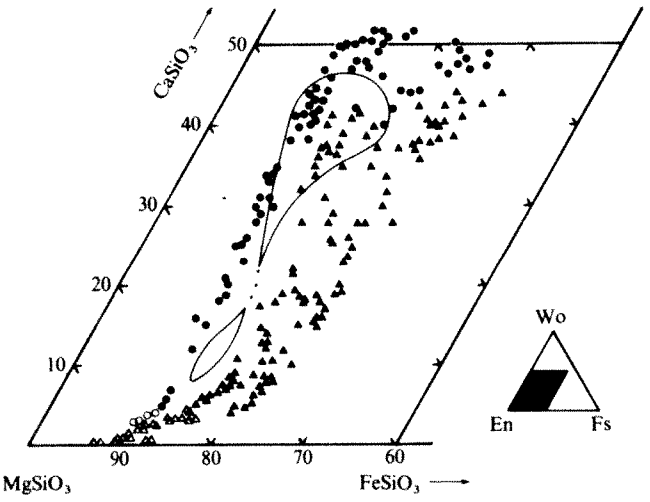

Fig. 2 Compositional variation of calcium-poor (open symbols) and groundmass calcic pyroxenes (closed symbols) within portion of the system $MgSiO_3$–$FeSiO_3$–$CaSiO_3$. All Fe is expressed as Fe^{2+}. Origin of specimens; ○●, Cyprus and Othris; △▲, Bonin Island, C. Vogel, Mariana Trench. Only a representative portion of augite analyses are shown. Field (enclosed) for basaltic komatiites from ref. 27 and this work. Analyses by energy-dispersive electron probe operated at 20 kV and 30 nA. Trace elements mentioned in the text were determined on a Geoscan instrument operated at 20 kV.

Groundmass calcic pyroxenes, however, are ubiquitous and typically have skeletal forms[28] and metastable compositions, evidence of supercooling and rapid growth. In boninites, the bulk of the quench pyroxene is aluminous augite but in a few examples from each locality except Othris, pyroxene is zoned continuously from pigeonite to augite; spot analyses selected to show the range of compositions are given in Fig. 2.

Table 2 and Fig. 2 show that samples from the Western Pacific have a different compositional trend with crystal growth from those associated with ophiolites. The Bonin Islands calcic pyroxene trend is the most magnesium-rich of the Pacific types whereas the Cape Vogel one is the least. More magnesian by far is the Cyprus trend which meets the least calcic of the Othris pyroxenes at about Wo_{38}. The crystallisation trends are specific to each locality and probably represent differing thermal histories just before eruption as much as fundamental differences in parent liquid compositions.

Orthopyroxene is rare in komatiites and so far has been positively identified only as a cumulus phase in the thick submarine flows of basaltic komatiite composition from the Abitibi belt of Ontario[24,27]. The variation in composition of groundmass pigeonite–augite is very similar to that of boninites. The data given in Fig. 2 are for pyroxenes in a pyroxene–spinifex top to a thin flow from the Belingwe belt and in ref. 24. Most basaltic komatiites, however, and all peridotitic komatiites, contain only augite and sub-calcic augite.

Deep red-brown magnesiochromites occur in almost every section of boninite or basaltic komatiite. Typically they are <0.03 mm across, euhedral and surrounded by glass. We detected zoning in one phenocryst only, from $Mg/(Mg+Fe^{2+}) = 0.683$ at the centre to 0.669 on the margin. All spinels are very chromium rich (Fig. 3) and have $Fe^{3+}/(Fe^{3+}+Al+Cr)$ ratios <0.1. Those in boninites from the Western Pacific have higher $Cr/(Cr+Al)$ ratios than those in the komatiite samples, whereas those from ophiolites span the whole range. Chromites in basaltic komatiites were found to have $Mg/(Mg+Fe^{2+}) < 0.6$. Figure 3 emphasises the peculiar composition of these spinels contrasted with those found in typical Mid-Atlantic Ridge basalts[29–31]; comparable compositions occur in the Great Dyke[32] and the Troodos plutonic complex itself[33].

Basaltic komatiites of comparable MgO contents to boninites commonly have a groundmass of microlitic plagioclase (0.2 by <0.01 mm) which we have determined, in one sample, to be An_{64}. Samples from the cores of boninitic pillow lavas from Othris and Cyprus display a similar plagioclase morphology but only rarely is the feldspar unaltered. In the Upper Pillow Lavas from Cyprus values of An_{65-75} were obtained and more calcic compositions (up to An_{95}) have been reported from ultramafic lavas[25]. Several boninite specimens from each locality, except the Bonin Islands, contained tiny laths, stellate aggregates or dendrites of green hornblende concentrated in the centres of pools of glass. The textures indicate that they are of primary origin, demonstrating the hydrous nature of the magma. In addition, rosettes of biotite up to 0.3 mm across occur in one specimen from the Mariana Trench[15] and several of the ultramafic (olivine–phyric) lavas from Othris. Perfectly isotropic glass in the boninites has a water content of 6–8% (microprobe, by difference) but it is unlikely that all of it is original.

Primary hydrous phases are very rare in komatiites. Arndt[23] has described cumulus brown hornblende from close to the centre of one of the basaltic komatiite layered flows mentioned earlier but we could find no evidence of original groundmass hornblende in the least altered Rhodesian samples.

Boninites and komatiites are very similar in both mineralogy and texture. With the exception of the spinifex olivine rocks from Gorgona Island[34], which we do not consider are boninites because neither are they quartz normative nor do they have large modal amounts of hydrous glass, boninites are unique in this respect amongst Phanerozoic rocks. The only notable mineralogical differences between basaltic komatiites and boninites lie in the relative paucity of orthopyroxene and hornblende and high chrome contents of olivine in the former.

Chemical composition

The chemical compositions of boninites and basaltic komatiites are similar (Tables 1 and 2) and both have $Mg/(Mg+Fe)$ ratios appropriate for primitive liquids in equilibrium with mantle olivine[35]. The lavas of the Arakapas fault belt have been called basaltic komatiites, largely on geochemical grounds[12], but this was rejected[4] because of the significantly lower incompatible element contents, notably titanium, of those rocks and what we term boninites from Cape Vogel and the Mariana Trench. The TiO_2 contents of the Othris samples (Table 2), however, assuming that titanium is a relatively immobile element during alteration, are comparable with those of basaltic komatiites, as are their CaO/Al_2O_3 ratios calculated from the less altered ultramafic (olivine–phyric) lavas. The CaO/Al_2O_3 variation between different boninites is faithfully recorded in the pyroxene compositions: in Othris there are no low-calcium pyroxenes or sub-calcic augites, in the Cape Vogel and Mariana Trench rocks clinoenstatite occurs while the Bonin and Cyprus

altd, mineral in pseudomorph form only; —, mineral or pseudomorph not observed; *, larger crystal. Mineral compositions are from this study except for the Canadian data (refs 23, 24 and 27); whole rock compositions include data from refs 6, 9, 11, 12, 15, 21 and 23; Fe^{2+} calculated on the basis of $Fe^{3+}/(Fe^{2+}+Fe^{3+}) = 0.1$.

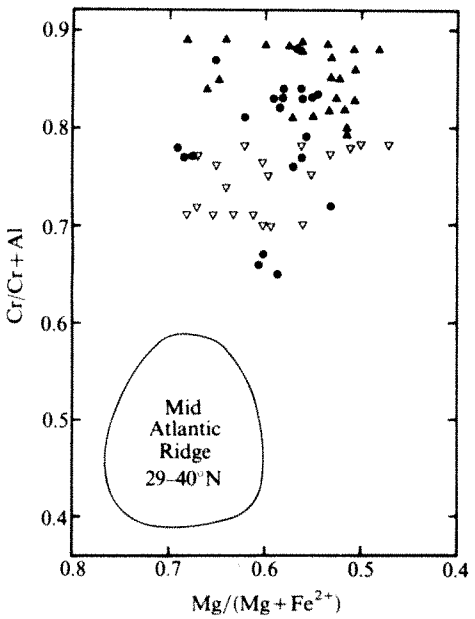

Fig. 3 Compositions of chromites from boninites (● and ▲ as Fig. 2) and basaltic komatiites (▽), projected onto the Fe^{3+}-free face of the spinel prism. Analyses by energy-dispersive electron probe, Fe^{2+} estimated by assuming stoichiometry. Field of Mid-Atlantic Ridge spinels from refs 29–31.

material has orthopyroxene as the low-calcium phase. In this context, basaltic komatiites are intermediate between the Cyprus and Othris examples. We conclude that a spectrum of titanium contents and CaO/Al_2O_3 ratios exists in boninites and each overlaps the range found in basaltic komatiites. This may result from differing degrees of melting, mantle inhomogeneity or chemical evolution of the mantle with time.

We are not entirely convinced that boninites have much lower Ti/Zr than chondritic values[4]. The Upper Pillow Lavas of the Troodos Massif, those in the Arakapas Fault bewt and Agrilia Formation of the Othris Mountains have average Ti/Zr ratios of 100, 105 (ref. 12) and 94 respectively, close to chondritic values and basaltic komatiites (ranging from 60 to 140 in 50 samples).

Origin

Curiously, the origin of boninite would seem to be among the least controversial of any rock type. Green's carefully controlled experiments on water-saturated partial melting of pyrolite[36] produced a liquid at 1,200 °C, 10 kbar (~35% melting) which he calculated to have 54% SiO_2, 14% MgO, an Mg/(Mg+Fe) ratio of 0.73 and $CaO/Al_2O_3 = 0.88$, the chief characteristics of boninite. Melting of a mantle segment that has been depleted in incompatible elements by previous melting episodes would require very high temperatures[37] to produce such magnesian liquids. It is difficult to imagine such temperatures in Phanerozoic mantle melts, thus we postulate that this could be achieved only by a 'wet' process, whereas in the Archaean with less depleted mantle and possibly higher geothermal gradients, melts of similar or even more magnesian composition were generated by 'dry' melting. Basaltic komatiites were probably comagmatic with peridotitic komatiites, having arisen by low-pressure fractionation first of olivine, then augite from parental magmas with about 25% MgO[23,21,38]. Sun and Nesbitt suggested that the term komatiite should have the petrogenetic constraint that it is derived by dry melting of a mantle (with relatively undepleted incompatible element contents)[4]. Two observations are unexplained: the rare appearance of hornblende during fractional crystallisation of basaltic komatiites[23,27] and the apparent scarcity of rocks with compositions lying between 16 and 20% MgO; basaltic and peridotitic komatiite[21].

There are great similarities between boninites and basaltic komatiites but the association of the latter with liquids of ultramafic composition is characteristic of the Archaean alone. It is tempting to speculate that the petrogenesis of basaltic komatiites and boninites differs from that of peridotitic komatiites by involving water, but the evidence presented above is inconclusive. We regard boninite therefore as petrographically, mineralogically and chemically the closest Phanerozoic equivalent to basaltic komatiite; the fundamental differences arising from changes in the Earth's mantle and thermal and tectonic regimes between the Archaean and the Phanerozoic.

It is significant that boninites are almost exclusively associated with ophiolites (but not necessarily vice versa). Troodos, Othris and the Canadian Palaeozoic examples[17,19] form part of the extrusive sequence in well documented ophiolites. The igneous rocks from the Mariana dredge at 12° N are all of the 'ophiolite association'[14].

Boninites from the Western Pacific are in identical fore-arc tectonic settings on the 'mid-slope high' (ref. 39). It is possible that boninites, and by implication ophiolites containing boninitic lavas, were formed *in situ* by partial melting of peridotite overlying the downgoing slab and that the associated two-pyroxene andesites and dacites[5] are manifestations of a steadily evolving boninitic liquid from an island-arc setting[6]. There are two main problems with this view: the fact that the active volcanic chain in the Western Pacific is 150 km further away from the trench than the mid-slope high and that the overlying slab would be too cool. One possibility may be that boninites are erupted in the initial stages of breaking an older oceanic plate. It is very unlikely that boninites represent material scraped off the oceanic plate—they share none of the petrographic or geochemical characteristics of basalts generated at mid-ocean ridges over the past 180 Myr.

The planktonic foraminiferal species Globigerinoides ruber *with pink-pigmented tests occupied a worldwide warm-water belt during much of the Pleistocene. This variety was exterminated from the Indian and Pacific Oceans at about 120,000 yr BP, based on the oxygen isotope stratigraphy in 11 Indo-Pacific deep-sea cores, but it continued to live on to the present in the North and South Atlantic Ocean and the Mediterranean Sea. The disparate Atlantic and Indo-Pacific records reflect faunal provincialism that has been developing in the two regions since the Pliocene.*

THE pink-pigmented variety of *Globigerinoides ruber* (d'Orbigny) forms a large proportion of the planktonic foraminiferal fauna of the modern Atlantic Ocean[1–11] and Mediterranean Sea[12], but is completely absent from the present-day Indian and Pacific Oceans[13–18]. This foraminiferal variety did, however, occur in a circum-global warm-water belt during the late Pliocene and Pleistocene. Here we document the timing and geographic extent of the disappearance of pink-pigmented *G. ruber* as a synchronous extermination throughout the tropical and subtropical Indo-Pacific at 120,000 yr BP (the beginning of the last full interglacial and the lower part of oxygen isotope stage 5). We have relied on $\delta^{18}O$ curves for direct worldwide correlation of this biostratigraphic event because the fluctuations of these curves reflect global ice volume[19] and are nearly isochronous within the time constraints of ocean mixing[20]. The apparent diachroneity of the Atlantic and Indo-Pacific stratigraphic records of coloured *G. ruber* since 120,000 yr BP may be related to faunal provincialism which has been developing in tropical latitudes since the Pliocene[21].

Indo-Pacific sediments

Although pink-pigmented *G. ruber* has not been reported from either the plankton or Recent sediments of the Indian and Pacific Oceans, it is occasionally listed from the Pleistocene and rarely from older sediments. Cushman *et al.*[22] and later Todd[23] reported small red and faintly pink specimens from Bikini and Eniwetok Atolls. Brönnimann and Resig[24] found pink *G. ruber* in the Pleistocene of Deep Sea Drilling Project Site 62 in the western equatorial Pacific and Jenkins and Orr[25] found it in the Pliocene and Pleistocene of eastern equatorial Pacific DSDP sites. Thompson[26] reported an acme of pink-pigmented *G. ruber* between solution cycles III_p and II_p (250,000–124,000 yr BP) in the western tropical Pacific, and placed the top of its range near the 6/5e oxygen isotope boundary.

We have taken samples at 10 cm or closer intervals for $\delta^{18}O$ measurements and total faunal analyses from many piston cores (Table 1; Fig. 1) to delineate the extermination datum level. The samples for isotopic analyses were roasted under vacuum at

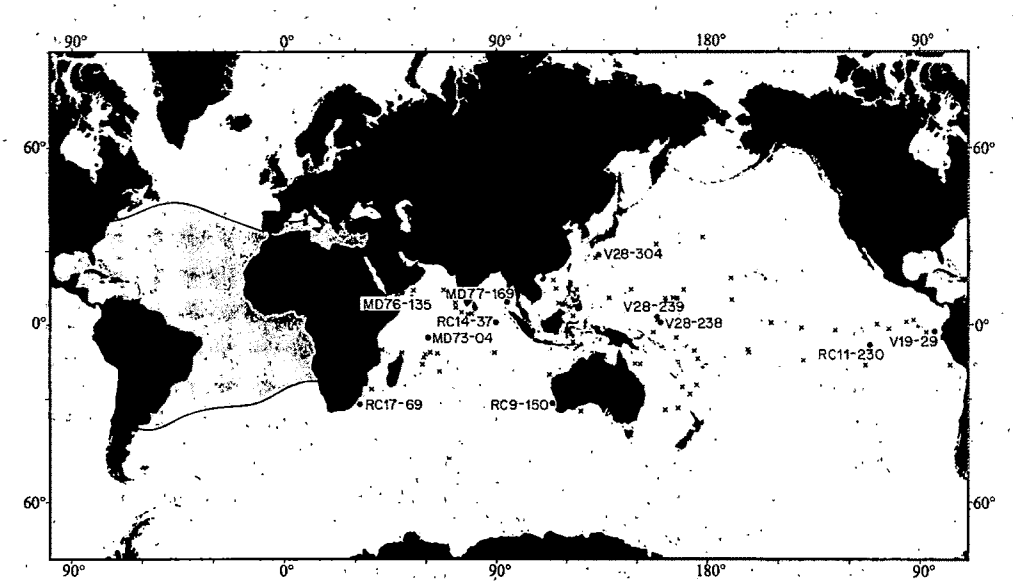

Fig. 1 Locations of piston cores with pink-pigmented *G. ruber* 120,000 yr BP datum and oxygen isotope records (dots), and other downcore occurrences of pink-pigmented *G. ruber* (crosses) in the Indo-Pacific. Pink-pigmented *G. ruber* survived in the Atlantic Ocean and Mediterranean Sea where it occurs in Quaternary sediments and present-day warm-water region (shaded).

Table 1 Cores used in this study

Core	Lat	Long	Water depth (m)	Core length (cm)	Isotopic reference	Occurrence level of 6/5e* boundary in core (cm)	Top occurrence of *G. ruber*† in core (cm)	Age of datum‡ (yr BP)

* Given by Shackleton and Opdyke[19] as 128,000 yr BP.
† Pink-pigmented form.
‡ Interpolated from 6/5e boundary and sample interval.

400 °C for 45 min and reacted under vacuum with 100% H_3PO_4 at 50 °C; the $^{18}O/^{16}O$ ratio is reported as $\delta^{18}O$ relative to the Chicago Pee Dee Belemnite (PDB-1) standard:

$$\delta^{18}O = \left[\frac{(^{18}O/^{16}O)_{sample}}{(^{18}O/^{16}O)_{standard}} - 1\right] \times 1{,}000$$

Faunal studies are based on a minimum count of 300 individuals greater than 149 μm in diameter to ensure statistical reproducibility. To take into account the effect of carbonate dissolution on the absolute abundances of total *G. ruber* populations through time[26], downcore variations have been expressed as the ratio of pink to total *G. ruber*.

The oxygen isotopic records[27–32] and stratigraphic ranges of pink *G. ruber* for six Indian Ocean and five Pacific Ocean cores are shown in Figs 2 and 3. The curves were plotted to align isotopic stage 5e. Marked stage-to-stage sediment accumulation variations point to the effects of local depositional characteristics. The lithostratigraphic top of the range of pink *G. ruber* consistently lies within stage 5. Furthermore, cores with slow deposition rates, such as RC17-69, RC14-37, V28-238 and V28-239, show higher vertical occurrences than cores with high rates of accumulation such as MD76-135, MD77-169 and V19-29.

Isotopic measurements on both pink and white forms from stages 7 to 5e of core MD77-169 are shown in Fig. 4. Pink *G. ruber* is 0.17‰ lighter (s.d. 0.14) than the white form. Too few specimens were recovered from samples at the 5e maximum (880 and 890 cm) to analyse, but the light isotopic composition of the pink shells at 900 cm shows that these individuals lived after the 6/5e transition. The abundance of pink *G. ruber* shells decreases from 950 to 900 cm; at 900 cm, bioturbation will introduce isotopically heavy shells deposited in stage 6, but the same bioturbation cannot introduce isotopically lighter shells from higher up in stage 5e because the variety has already disappeared. Therefore, bioturbation will produce isotopically heavier measurements if the pink form is analysed rather than the white form, which can still be contaminated from stage 5. The true (chronostratigraphic) level for the top of the range of pink *G. ruber* is probably above the 5e/6 transition but before the 5d interglacial stadium. The occurrence of pink specimens above this level is attributed to sediment mixing by bioturbation[33–35]. Thus, in cores with rapid sedimentation rates, the level of highest lithostratigraphic occurrence is closer to the true disappearance level than it is in cores with slower accumulation rates, where an equivalent amount of bioturbation can disturb sediments representing a longer period of time.

The ratio of coloured-to-total *G. ruber* shows a consistent pattern down the cores. In the late portion of oxygen isotopic stage 6, the ratio averages 10%. It drops to 0% in the early part of stage 6, quickly returns to 10% or more in stage 7, and climbs to 20–25% in stage 8. In the two subtropical cores RC17–69 and RC9–150, the overall proportions of *G. ruber* are lower than in the more tropical cores reflecting the higher latitudes of the sites, but the downcore pattern of pink *G. ruber* ratios is similar to other cores studied. In all cores, abundances decrease rapidly below isotopic stage 10. In the early Brunhes and late Matuyama sections of V28–238 and V28–239 pink *G. ruber* was noted only from intervals of low carbonate dissolution. Specimens from these samples show a very faint colouration, fading downcore to the extent that they become indistinguishable from the colourless (white) form. Thus, we conclude that first occurrences in the middle of the Pleistocene do not necessarily mark an abrupt evolutionary appearance at this time, but are probably due to a progressive improvement in preservation of the pigment.

There is a possibility that pigmented and non-pigmented *G. ruber* may be differentiated on a morphological basis. If, as Hecht[36] suggests from a study of living Atlantic forms, the pigmented varieties are larger in size with wider apertural openings and a higher spire than the white (non-pigmented) type, this morphology may enable us eventually to place a lower age limit on the range of the coloured type despite its fading.

Atlantic sediments

In the North and South Atlantic, pigmented *G. ruber* occurs in the modern-day plankton and in sediments from middle Pleistocene to the Recent. It is most abundant in the boundary currents including the Gulf Stream, Antilles, Canaries, and Brazil Currents, and near Caribbean islands; it seems to be less abundant in regions away from land masses, such as the central Sargasso Sea, the central equatorial Atlantic, and the central South Atlantic[1–11,37]. The distribution pattern generally coincides with temperature maxima of surficial waters, and seems to avoid upwelling areas[38,39]. A strong seasonality has been observed in middle latitude regions[40,41] where the white form predominates during the colder times of the year and the pink form in warmer periods. The pigment intensity increases from pink to deep ruby red with increasing temperatures. Bé and Tolderlund[10] observed a seasonal 'migratory' trend of pigmented

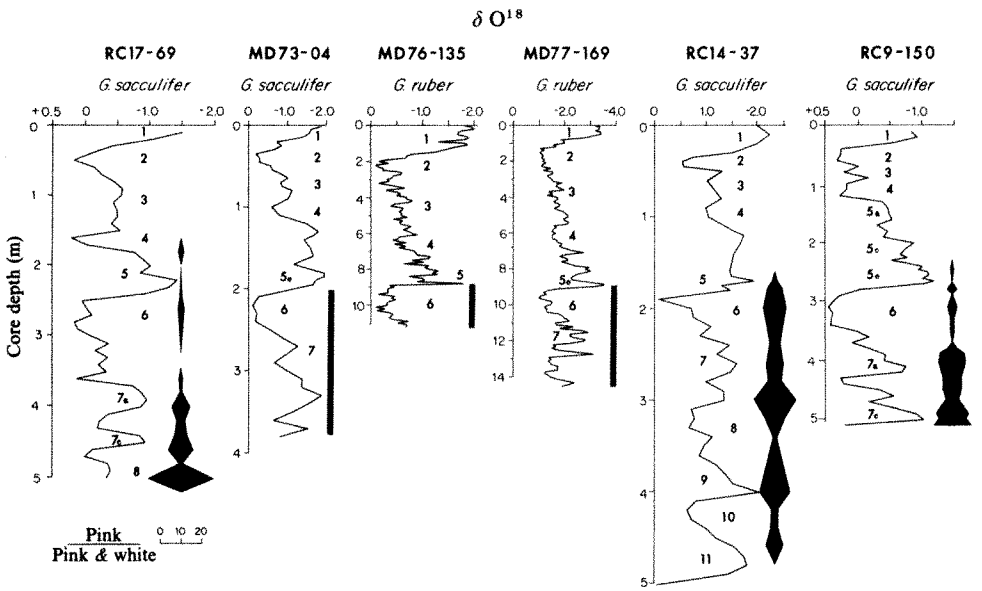

Fig. 2 Indian Ocean cores showing extermination datum of pink-pigmented *G. ruber* and oxygen isotope records (relative to PDB). Dark shading is the % ratio of pink to total *G. ruber*; light shaded line is occurrence of pink *G. ruber* in the core without quantitative measures.

G. ruber populations in the North Atlantic between the Caribbean and regions north of Bermuda. A front of pink *G. ruber* 'moved' northwards from spring to late autumn due to increasing numbers of pink *G. ruber* that developed pigmentation in response to locally elevated temperatures. A reverse southward 'migration' was observed from late autumn to early spring.

Surface sediment distributions of pigmented *G. ruber* closely follow plankton distributions in the North[1–11] and South Atlantic (Fig. 1). The northern limit runs approximately from Nova Scotia in a slightly northerly bulging arc to Spain, whereas the southern limit runs obliquely from Golfo San Matias (Argentina) to Walvis Bay (Namibia). Pink *G. ruber* is absent south of Walvis Bay both in the plankton and surface sediments, indicating that a barrier presently exists which prevents the South Atlantic population from entering the Indian Ocean. Similarly, the South American continent's extension to 55 °S latitude effectively blocks pink *G. ruber* from the Pacific Ocean. The highest proportions of the coloured variety underlie tropical areas of high surface temperature. Both pigmented and non-pigmented *G. ruber* occur in highest percentages on topographically shallow areas where carbonate dissolution is relatively low.

The tendency for pigmented tests of *G. ruber* to be associated with warm oceanic regions seems to be substantiated by downcore studies. Most studies that have distinguished pink from white *G. ruber* have noted two trends reflecting latitudinal occurrence. Low-latitude cores from the Gulf of Mexico, Caribbean and central Atlantic contain both types of *G. ruber* throughout glacial and interglacial stages[42–45]. Cores from subtropical and temperate regions, the Mediterranean[46], and the late Pliocene–early Pleistocene Le Castella section in Italy[47,48], contain pigmented forms only during warm, interglacial stages.

Discussion

The pigmentation in *G. ruber* has been preliminarily identified as the organic compound pheophytin, a carotene[7], incorporated into the test wall. The intensity of colouration is greatest in the earliest-formed chambers and typically becomes progressively lighter in later chambers. The final chamber may vary from

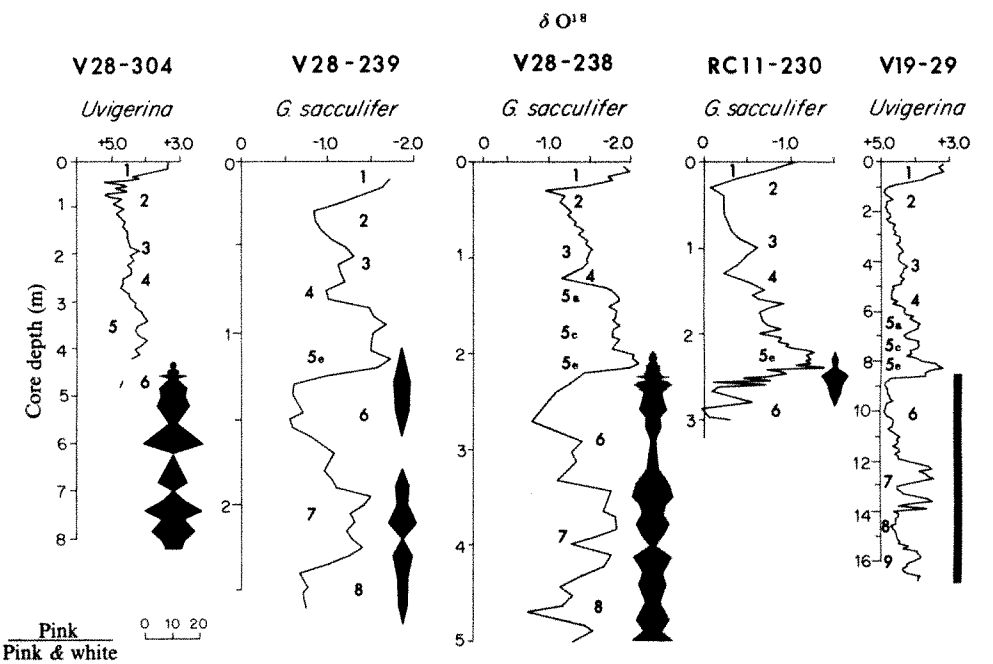

Fig. 3 Pacific Ocean cores with pink-pigmented *G. ruber* datum and oxygen isotopes. See also Fig. 2. Note that *Uvigerina* is absent during stage 5e (420–460 cm) in V28-304.

intensely pink to colourless. The origin and function of the pigmentation are unknown, but may be related to the large quantity of symbiotic zooxanthellae harboured within the protoplasm[49,50]. This light-dependent symbiosis requires *G. ruber* to have a near-surface warm-water habitat, which has been verified by plankton tows[7,10] and, ultimately, gives the species its relatively light oxygen isotopic composition[51,52].

In the Indo-Pacific sediments examined, the pigment intensity is generally much less than in the Atlantic. The Pacific forms are either light pink throughout or are light red in the early chambers, later becoming white. The deep red colouration and large test size common to the tropical Atlantic and West Indies are rare in the Pacific. We suggest that the intensity of colouration is related to vital (and perhaps genetic) factors controlling the production of the pheophytin such as nutrient supply, light intensity, surface temperature, and possibly symbiont type and proximity to land masses. Orr[25,49] has also interpreted the intensity of pigmentation as a qualitative indicator of sedimentation rate.

The oxygen isotopic change of 1.5–1.8‰ in most records across the 6/5e transition demonstrates a drastic, worldwide ice-volume shift in a period of only several thousand years. Isotopic values (see Figs 2 and 3) indicate that stage 6 was one of the longest glacial periods of the Quaternary. The white *G. ruber* form can be found throughout the Pleistocene and Recent Indo-Pacific warm-water region and seems to have suffered no detrimental effects. The persistence of pink forms to the base of stage 5e (Fig. 4) indicates that it lasted through stage 6 to the time of initiation of stage 5 conditions. Again we return to the nature of the pigment and its source. If dinoflagellate symbionts produce the pigment, the extermination may be due to the elimination of the symbionts and thus their host, whereas the species of symbiont in white *G. ruber* would have been unaffected. If production of the pigment is operated by *G. ruber* itself, a case can be made that pink *G. ruber* may be a separate subspecies from the white form. In either case, the disappearance of pigmented *G. ruber* is an important palaeoecological indicator of some natural condition(s) that dropped below, or was raised above, a critical tolerance.

The absence of pink *G. ruber* in the Quaternary and modern Indo-Pacific region may be further evidence of a faunal provincialism that developed between the Atlantic and the Indo-Pacific Oceans after the separation of the Atlantic from the Pacific by the emergence of the Panama Isthmus in the late Pliocene[21]. Rare occurrences of pink *G. ruber* are reported from the late Pliocene from both sides of the Isthmus[25,42,47]. Other evidence of Quaternary faunal provincialism is in a reversed sense of that of pink *G. ruber*. Thus, the planktonic foraminiferal species *G. adamsi*, *G. hexagona*, *G. conglomerata*[45,53], *G. pseudofoliata* (ref. 26) and *Globorotalia menardii neoflexuosa*[54–56] occur in Quaternary sediments and present-day waters

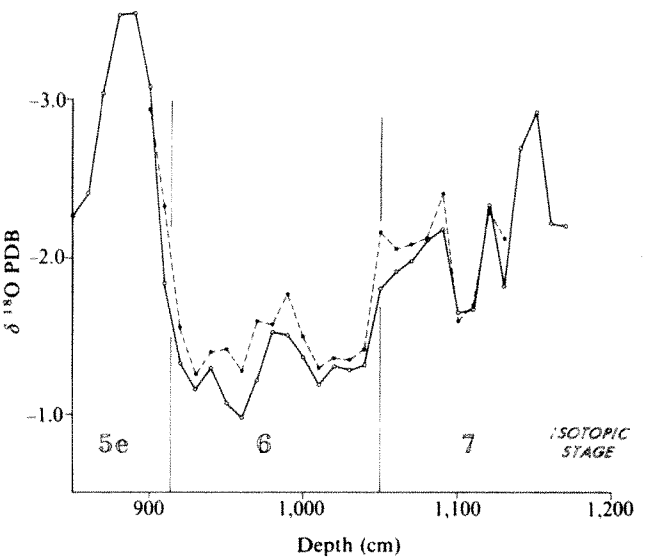

Fig. 4 Isotopic values of pink (●) and white (○) *G. ruber* in core MD77-169. The values show that the pink form lasted into stage 5e.

of the Indo-Pacific, but are absent in the Atlantic during this period. In addition, the coiling direction histories of *Pulleniatina* have diverged into two distinct patterns since the closing of the Panama Isthmus[57,58]. We suspect that the Panama Isthmus emergence, the migrational barrier presented by the Agulhas Current flowing around the Cape of Good Hope with the relatively high latitudinal location of the southern boundary of the African continent at ~35 °S, and the extension of South America to 55 °S, may all have led to the development of genetic differences between Atlantic and Indo-Pacific populations of *G. ruber* which proved fatal to the latter during the earliest portion of oxygen isotope stage 5e. Their disappearance occurred soon after a rapid climatic transition which probably placed a certain stress on the population. Whatever the exact cause of the extermination of pink-pigmented *G. ruber* at 120,000 yr BP, stratigraphers now possess a most useful and widespread datum for the identification of the oxygen isotope 5e/6 transition throughout the Indo-Pacific area.

We thank W. Prell, W. R. Ruddiman and A. Boersma for discussions. Support for our studies was provided by NERC grants GR 3/768 and GR 3/1762 (N.J.S.), Les Terres Australes et Antarctiques Françaises (J.C.D.), NSF grants GA 38276 and OCE 78-25450 (A.W.H.B.) and NSF grants OCE 75-18136 and OCE 77-22893 (P.R.T.). LDGO cores were collected and curated under Office of Naval Research grant N00014-C-0210 and NSF grant OCE 76-18049.

Temperature-dependent X-ray diffraction as a probe of protein structural dynamics

Hans Frauenfelder, Gregory A. Petsko* & Demetrius Tsernoglou

X-ray diffraction at four temperatures from 220 to 300 K coupled with crystallographic refinement yields the mean-square displacements and conformational potentials of all 1,261 non-hydrogen atoms of metmyoglobin. The results are interpreted to indicate a condensed core around the haem, semi-liquid regions towards the outside and a possible pathway for ligands. It is concluded that X-ray diffraction can provide the spatial distribution of the dynamic features of a protein.

TRADITIONAL X-ray models present proteins as static molecules of unique structure. Experimental findings and theoretical arguments, however, indicate that they are fluctuating systems[1,2]. A protein in an equilibrium conformation can exist in a very large number of conformational substates; proteins in different substates have the same coarse structure but differ in local configurations. Rotations about single bonds or shifts of hydrogen bonds may occur. The experiments of Austin *et al.* imply that all conformational substates have the same biological function, but possibly at different rates[3]. As transition from one substate to another generally occurs by overcoming a potential energy barrier, the dynamic behaviour of proteins depends on temperature. At sufficiently high temperatures, a protein molecule moves rapidly from one substate to another, breaking and reforming non-covalent bonds and changing the structure continuously. At low temperatures, much of this conformational relaxation is lost and each molecule remains in a particular substate. The experimental evidence for a fluctuating protein comes from many different techniques. Flash photolysis data at low temperatures imply the existence of many conformational substates[3,4]. Intramolecular motions have been inferred from fluorescence quenching[5] and relaxation[6], NMR[7–9], and isotope exchange[10,11]. Theory implies that a molecular system of N components (amino acids) has approximately e^N states with energies close to that of the ground state[12] and experiences sizeable fluctuation in internal energy, entropy and volume[13]. Because binding is 'strong' ($\gg k_BT$) along the polypeptide backbone and 'weak' ($\approx k_BT$) in other directions, a biopolymer may form a globule, with a condensed core and a diffuse outer phase[14]. A computer solution of the equations of motion of the atoms in a globular protein suggests a fluid-like interior, atoms displaced from their equilibrium position by up to 2 Å, and fluctuations on a picosecond time scale[15].

The experimental evidence for the effect of substates on the binding of carbon monoxide to myoglobin[3] has prompted us to investigate whether conformational substates can be observed by X-ray diffraction. Consider a typical globular protein such as myoglobin. X-ray diffraction permits the determination of the mean-square displacement, $\langle x^2\rangle$, of all atoms except hydrogen. The temperature dependence of $\langle x^2\rangle$ should reveal regions of conformational flexibility. In this article, we outline the features underlying the determination of $\langle x^2\rangle$, describe the experimental approach and present data which support the picture of a fluctuating protein.

Atomic displacements from X-ray scattering

X-ray scattering can determine not only the position, but also the mean-square displacement, $\langle x^2\rangle$, of a scattering particle[16]. For an atom in a protein crystal, $\langle x^2\rangle$ can at a first approximation be written as

$$\langle x^2\rangle = \langle x^2\rangle_c + \langle x^2\rangle_d + \langle x^2\rangle_{ld} + \langle x^2\rangle_v \qquad (1)$$

The subscripts stand for conformation substates, diffusion, lattice disorder and vibration, respectively. The term $\langle x^2\rangle_d$ is due to translational and rotational diffusion and depends on T/η, where T is the temperature and η the viscosity of the crystal. The term $\langle x^2\rangle_{ld}$ is caused by macroscopic disorder in the protein crystal. Even if all protein molecules were identical, the crystal would possess some disorder. Disorder should be almost temperature independent and, if purely translational, contribute equally to all atoms in the protein. The vibrational term, $\langle x^2\rangle_v$, contains components from individual atoms[17], groups of atoms, and the entire molecule (rigid-body motion). The main contribution comes from the vibration of groups of atoms. In the Debye approximation, $\langle x^2\rangle_v$ is constant well below the Debye temperature T_D and proportional to T above T_D (Fig. 1*b*)[16].

The conformational term, $\langle x^2\rangle_c$, is of central interest here. If proteins are fluctuating systems with many conformational substates, each atom or group of atoms will be able to occupy different substates, as shown in Fig. 1*a*, which gives the conformational potential, V_c, as a function of the distance from the mean position. The substates correspond to local minima in V_c. Above a relaxation temperature, T_r, each atom will rapidly move from one substate to another; the substates are in equilibrium and populated according to a Boltzmann distribution. Below T_r the atoms can no longer overcome the barriers between substates and each atom remains in a particular substate. X rays interact with a rapidly fluctuating and a 'frozen' protein in the same way: X-ray diffraction measures the spatial distribution over conformational substates in the fluctuating and the frozen state. The temperature dependence expected for $\langle x^2\rangle_v$, for $\langle x^2\rangle_c$, and for their sum is shown in Fig. 1*b*. The conformational potentials and the barriers between substates depend on the local structure and may change with temperature. The relaxation temperature may differ from atom to atom; the value indicated in Fig. 1*b* implies an average.

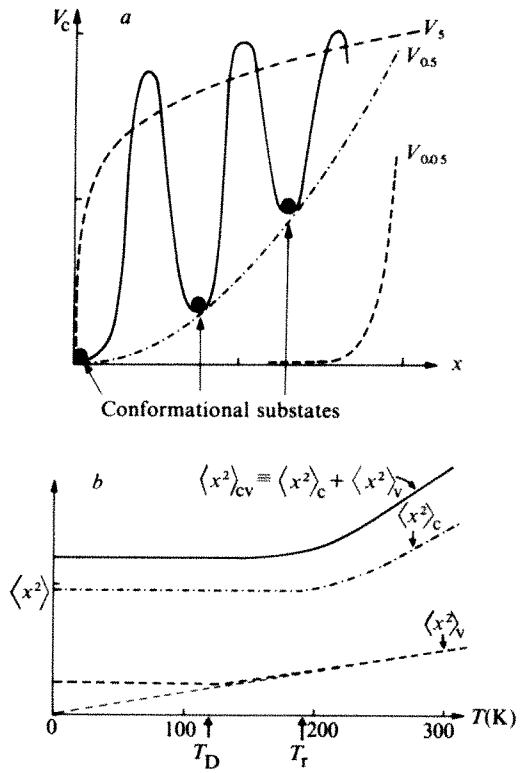

Fig. 1 *a*, The local minima in the conformational potential V_c, given by the solid line, represent conformational substates. The bottoms of the wells are parametrised by power laws, $V_v \alpha x^{1/\nu}$, and three cases are shown as dashed lines. *b*, Temperature dependence of the conformational ($\langle x^2\rangle_c$) and vibrational ($\langle x^2\rangle_v$) mean-square displacement.

The distinction between vibrational and conformational contributions to $\langle x^2\rangle$ is to a certain extent a matter of definition. One way of separating the two terms is by their low-temperature limit. Vibrational contributions should converge towards a value typical for zero-point vibrations, whereas conformational substates can lead to a much larger value of $\langle x^2\rangle$.

Mössbauer effect

Independent information on $\langle x^2\rangle$ for some nuclei (for example, ^{57}Fe) comes from the recoil-less fraction, *f*, of the Mössbauer effect[18,19]. Each nucleus absorbs randomly, stationary disorder does not decrease *f*, and only conformational substates, diffusion[20] and vibrations must be considered. The time scale in the Mössbauer effect is set by the nuclear lifetime, τ_N (140 ns for ^{57}Fe); $\tau_c(T)$ will denote the temperature-dependent mean time for conformational relaxation. At a characteristic temperature T_c, τ_c is equal to the nuclear lifetime

$$\tau_c(T_c) = \tau_N \tag{2}$$

Well below T_c, τ_c is very long relative to τ_N and the Mössbauer effect is sensitive only to $\langle x^2\rangle_v$.

$$\langle x^2\rangle_{M\ddot{o}}(T \ll T_c) = \langle x^2\rangle_v \tag{3}$$

Well above T_c, τ_c is short relative to τ_N and the Mössbauer effect is sensitive to all terms in equation (1) except $\langle x^2\rangle_{id}$.

$$\langle x^2\rangle_{M\ddot{o}}(T \gg T_c) = \langle x^2\rangle_c + \langle x^2\rangle_d + \langle x^2\rangle_v \tag{4}$$

Data collection and structure refinement

Crystals of metmyoglobin have the symmetry of space group $P2_1$, with cell dimensions $a = 64.31$ Å, $b = 30.85$ Å, $c = 34.85$ Å, $\beta = 105.85°$, and one molecule of molecular weight 17,900 per asymmetric unit. One crystal of dimensions $1.1 \times 0.8 \times 0.5$ mm^3 was used for the measurements at 300 K, 275 K and 250 K. The crystal was in contact with its normal mother liquor containing 75% saturated ammonium sulphate and 0.1 M phosphate, *p*H 6.1 Measurements at 200 K were made on a different crystal of identical size and shape in which the normal mother liquor was replaced by 75% 2-methyl-2,4-pentanediol, 30% water and 0.02 M cacodylate buffer with proton activity $p\mathrm{H}^* = 6.1$ (ref. 21). This mixed solvent is a cryoprotectant for the crystals and permits measurements below the freezing point of the ammonium sulphate mother liquor[22].

X-ray diffraction data were recorded with a Syntex $P2_1$ diffractometer equipped with an LT-1 low-temperature device, both modified for protein crystallography. Data were collected by a limited ω-step-scan procedure with continuous checking for crystal movement. No movement was detected. An empirical background curve was fitted to the data[23], which were also corrected for absorption[24]. The crystals were chosen so that the absorption effect was small. The data set at each temperature consisted of over 22,000 independent measurements to 1.5 Å resolution. Only reflections with intensities greater than twice their estimated standard deviations were retained for the refinements, approximately 16,000 per data set. To ensure that the effects of radiation damage were not misinterpreted as increased *B* factors on going to 300 K, data at 300 K were collected first, followed by the sets at 250 K and 275 K. Only 4% radiation-induced decay in diffraction intensities was observed at 300 K, and no significant radiation damage was detected at the lower temperatures.

Refinement of the metmyoglobin structure by the method of Konnert[25] as programmed by Hendrickson (personal communication) involves least-squares minimisation of the weighted sums of $|F_o - F_c|$ plus $|d_o - d_c|^2$. *F* denotes the structure factor, *d* the inter-atomic distance; the subscripts indicate observed and calculated. Proper choice of the relative weights produces a restrained least-squares fit in which the atoms are tethered to positions that maintain ideal bond lengths and angles. Refinement with restraints provides a sufficient ratio of observations to variable parameters to allow the refinement of positional coordinates and an isotropic displacement parameter, $B = 8\pi^2\langle x^2\rangle$, for every non-hydrogen atom. The starting point at each temperature was the refined 2.0 Å resolution structure of metmyoglobin determined by Takano[26], with a discrepancy index

$$R = \sum_{hkl} |F_o - F_c| \Big/ \sum_{hkl} F_o = 0.26$$

The structures have each been refined at 1.5 Å resolution to $R = 0.18$; the refinements took different numbers of cycles to reach this point, but were terminated at the same *R* to make the standard deviations comparable. Restraints on covalent and non-covalent bond distances have been set to preserve ideality within about 0.05 Å for covalent distances and 0.1 Å for the others. Side-chain atoms involved in restrained interactions will have $\langle x^2\rangle$ values that are correlated and possibly too small. Main-chain correlations might lead to $\langle x^2\rangle$ values systematically too large. Ordered water was observed on the surface of the protein, frequently in positions identical to those found by Takano[26]. These atoms were included in the refinement, but were not constrained.

Occasionally, the displacement parameters for a few atoms were found to increase with decreasing temperature, suggesting that the average position of the atom had changed, and the position being used in the refinement was no longer correct. This

Table 1 Average side-chain displacements at 250 K

	$\langle x^2\rangle_{cv}$(Å^2)	
Residue type	Outside	Inside
Charged	0.20±0.02	0.10±0.02
Neutral polar	0.16±0.04	0.08±0.04
Nonpolar	0.07±0.02	0.05±0.01

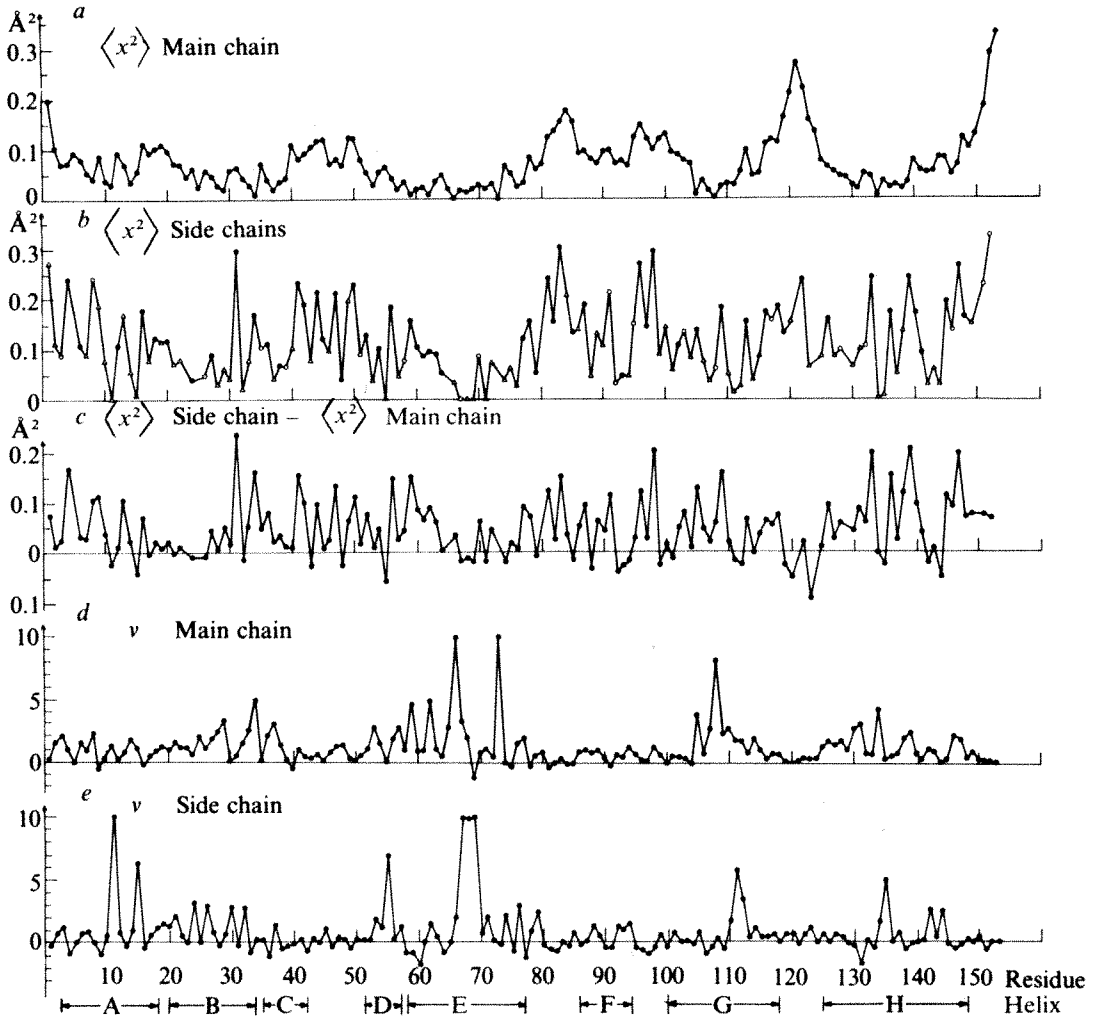

Fig. 2 *a*, The sum of the conformational and vibrational mean-square displacements, $\langle x^2\rangle_{cv} \equiv \langle x^2\rangle_c + \langle x^2\rangle_v$, averaged over the three main-chain atoms N, C^α and C, is plotted against residue number for myoglobin. *b*, The largest displacement in each side chain is plotted against residue number. ●, Hydrophilic; ○, neutral; △, hydrophobic residues. *c*, Difference between side-chain and backbone displacement. *d*, Exponent ν_b in the fit $\langle x^2(T)\rangle_{cv} = \text{const.}\ T^{2\nu}$, plotted against residue number for the main chain (backbone). *e*, Exponent ν_s for the largest side-chain displacement.

suspicion was confirmed by inspection of difference electron-density maps, which were calculated at several stages in the refinement process. Manual correction of the atomic positions led to reasonable temperature dependence in the next cycles of refinement.

In some cases, particularly for the 220 K structure, we observed the appearance of a new electron density at low temperature in positions suggestive of alternative conformations for side-chain atoms. Variable occupancy terms in the refinement may deal with this situation. Difference maps calculated at the present stage of refinement are virtually featureless for the 300 K, 275 K and 250 K structures.

The reliability of the displacement parameters has been checked by refining certain atoms, such as the iron, in a conventional, unrestrained least-squares refinement program. Over-determination was achieved by fixing the remainder of the structure. Cycles of restrained refinement have also been carried out after removal of the restraints on displacement parameters. Finally, a second set of 250 K data from a different crystal was measured and used to obtain refined parameters for comparison. From these results we estimate the standard deviation of our mean-square displacements to be 0.015 Å^2 for most atoms.

Determination of $\langle x^2\rangle_{cv}$

The evaluation described above gives $\langle x^2\rangle$ for all non-hydrogen atoms. Two assumptions underlie the standard treatment and are built into the current refinement methods: (1) $\langle x^2\rangle$ is isotropic; (2) the probability of finding a given atom a distance x from its mean position is gaussian

$$P_{1/2}(x) = P_{1/2}(0)\exp(-x^2/2\langle x^2\rangle) \quad (5)$$

For the exploratory extraction of $\langle x^2\rangle_c$, we add three more assumptions: (3) equation (1) holds; (4) diffusion can be neglected in crystals; $\langle x^2\rangle_d = 0$; (5) all atoms have the same temperature-independent value of $\langle x^2\rangle_{ld}$.

Assumptions (1) and (2) are certainly oversimplifications, but we retain them for the present. Assumption (4) is justified by the fact that the X-ray pattern is sharp even at 300 K. Assumption (5) is equivalent to considering the lattice disorder to be purely translational. Although we expect rotational disorder to be present, we have not yet assessed its magnitude. The fact that atoms on the protein surface have widely differing values of $\langle x^2\rangle$ indicates, however, that rotational disorder cannot be dominant.

Our eventual goal is the separate determination of $\langle x^2\rangle_c$ and $\langle x^2\rangle_v$. In the present study we will only determine their sum, $\langle x^2\rangle_c + \langle x^2\rangle_v \equiv \langle x^2\rangle_{cv}$. To extract $\langle x^2\rangle_{cv}$ from $\langle x^2\rangle$, we combine the results from X-ray and Mössbauer experiments and use the haem iron as calibration. Equations (1) and (4) show that $\langle x^2\rangle - \langle x^2\rangle_{M\ddot{o}}(T \gg T_r) = \langle x^2\rangle_{ld}$. Parak (ref. 27 and personal communication) has determined $\langle x^2\rangle_{M\ddot{o}}$ in metmyoglobin crystals up to 283 K, obtaining values of 0.037 Å^2, 0.061 Å^2 and 0.068 Å^2 at 250 K, 275 K and 300 K, respectively. Our X-ray data give $\langle x^2\rangle$ values of 0.091 ± 0.003 Å^2, 0.101 ± 0.003 Å^2 and 0.108 ± 0.003 Å^2, respectively, leading to $\langle x^2\rangle_{ld} = 0.045 \pm 0.006$ Å^3. Subtraction of this value from the measured X-ray results yields $\langle x^2\rangle_{cv}$ for all 1,261 non-hydrogen atoms of metmyoglobin. A table of all results at the four temperatures would be too long, and so we present in Fig. 2 only two numbers for each amino acid, the average for the backbone atoms N, C^α and C, and the value for the atom with the largest displacement in each side chain at 250 K.

As an indication of the size of $\langle x^2\rangle_v$, we note that linear extrapolation of the low-temperature Mössbauer data of Debrunner and coworkers[28] yields $\langle x^2\rangle_v \cong 0.02$ Å^2 at 300 K for the iron atom.

Structural dynamics of myoglobin

The data in Fig. 2 show that X-ray diffraction can provide an insight into the spatial distribution of the dynamic aspects of biomolecules. Phillips and coworkers have drawn similar conclusions[29,30].

Figure 2 provides evidence for conformational substates because $\langle x^2\rangle_{cv}$ reaches large values relative to typical vibrational displacements, and the large displacements are essentially temperature independent. Our Fig. 2 shows features similar to the prediction displayed in Fig. 2 of the paper by Karplus and coworkers[15]. Both prediction and experiment show very large displacements at the two terminals, the largest one occurring at the carboxyl end. To find a lower limit for the number of substates, in Fig. 2*c* the difference Δ between the values of $\langle x^2\rangle_{cv}$ for the backbone and the side chain are plotted for each residue as given in Fig. 2*a* and *b*. We arbitrarily assume that any residue with $\Delta \geq 0.025$ Å^2 has at least two conformational substates. About 95 residues satisfy this criterion, yielding $\geq 2^{95} \cong 10^{28}$ substates.

Figure 3 shows the static myoglobin structure as solid lines, areas reached by movements (at 250 K) of the backbone atoms shaded. The limiting excursion x_{lim} region is determined by setting $P_{1/2}(x_{lim})/P_{1/2}(0) = 0.01$ (equation (5)). Conformational substates still have a probability of 0.01 of being outside the shaded volume.

Figures 2 and 3 provide information on the conformational substructure of myoglobin. Figure 2*b* indicates that 44 residues have a maximum side-chain mean-square displacement larger than 0.15 Å^2. Almost all these lie on the surface of the protein. Of the 44, only 7 are hydrophobic. The observation of large values for $\langle x^2\rangle_{cv}$ on the surface implies a considerable interaction between solvent and protein. Table 1 gives the average values for the largest side-chain displacements, grouped according to type and position of the residue. Not surprisingly, displacements

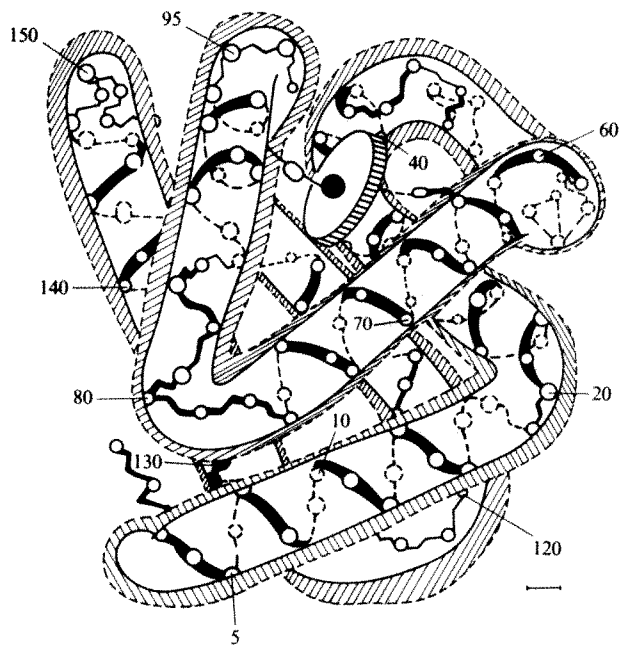

Fig. 3 Backbone (main chain) structure of myoglobin. The solid lines indicate the static structure as given in ref. 37. Circles denote the C$^\alpha$ carbons; some residue numbers are given. The shaded area gives the region reached by conformational substates with a 99% probability. Scale bar, 2 Å.

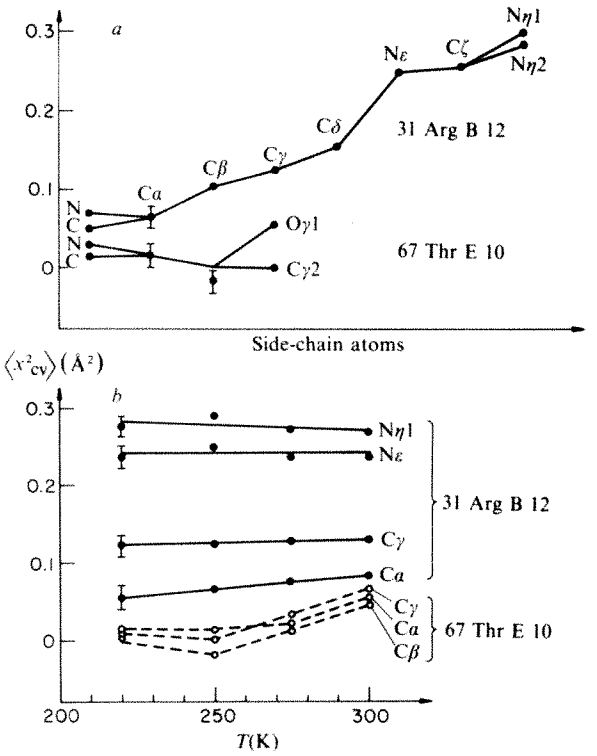

Fig. 4 Displacements $\langle x^2\rangle_{cv}$ for all non-hydrogen atoms of Arg 31 and Thr 67. *a* Shows the displacement at 250 K as a function of distance from the main chain; *b* gives the temperature dependence for some of the atoms. All points have the same estimated error; error bars are only shown on some.

are smaller inside the protein than outside. Charged and polar residues show larger displacements than the nonpolar ones, possibly because of charge fluctuations in the solvent and the hydration shell[1,2].

It is useful to follow the main chain, comparing $\langle x^2\rangle$ for both backbone and side chain with the position along the main chain. As already pointed out, the displacement is large whenever the side chain can extend into the solvent and small when other parts of the protein hinder the motion, as, for example, near residues 30, 60, 105 or 134. Even turns around the helix can be followed. Good examples are residues 10–14 in the A-helix, 25–28 in the B-helix and 73–76 in the H-helix, where the variation of $\langle x^2\rangle_{cv}$ around the helix is clearly seen. Similar periodicities occur in many places, suggesting that the helices do not move only as rigid units, but may also experience rippling or breathing modes. The accompanying article presents similar results for lysozyme[30].

The region around the haem is particularly interesting. On the distal side, near His 64, residues 39, 64, 67, 68, 71, 72 and 107 are in van der Waals contact with the haem group. The average $\langle x^2\rangle_{cv}$ at 300 K for the side chains is 0.04 Å^2, so that $x_{r.m.s.} = 0.2$ Å, comparable to values in many solids. These residues thus form a tight compartment around the binding site, guarding the access to the haem iron. Entrance to the pocket may be possible near residues 43–45, which are also on the distal side and have an average $\langle x^2\rangle_{cv} = 0.15$ Å^2. These residues are in the general region of one of the pathways found in a model calculation by Karplus and collaborators (D. A. Case and M. Karplus, in preparation). On the proximal side, near His 93, the situation is strikingly different. The average $\langle x^2\rangle_{cv}$ for the side chains in contact with the haem (42, 43, 89, 92, 97, 99, 103, 104, 138) is 0.12 Å^2. Moreover, the motion of the F-helix is also large. For haemoglobin, Perutz has suggested that this region is involved in a dynamic control mechanism[31]. The conformational displacement of the haem iron can be compared with the distribution in tunnelling distance observed in low-temperature flash photolysis[32]. If the conformational motion of Fe is perpendicular to the haem plane, $\langle x^2\rangle_{cv}(\text{Fe}) = 0.04$ Å^2 leads to $x_{r.m.s.}(\text{Fe}) = 0.35$ Å.

The tunnelling data imply an average spread in the tunnelling distance of approximately 0.3 Å in ferrous myoglobin.

Temperature dependence of $\langle x^2 \rangle_{cv}$

Additional information can be obtained from the temperature dependence of $\langle x^2 \rangle_{cv}$. We simplify the situation shown in Fig. 1 by assuming that each atom moves in a conformational potential, V_ν, indicated by dashed lines. We approximate the isotropic potential, $V_\nu(x)$, $x > 0$, by a power law

$$V_\nu(x) = \text{const.}\ x^{1/\nu} \tag{6}$$

Three different potentials are given in Fig. 1. At a temperture $T \gg T_r$, substates at distance x are populated according to a Boltzmann distribution

$$P_\nu(x : T) \propto x^2 \exp(-\text{const.}\ x^{1/\nu}/T) \tag{7}$$

The mean-square displacement for $T \gg T_r$ is given by

$$\langle x_\nu^2 \rangle = \int dx x^2 P_\nu(x; T) \Big/ \int dx P_\nu(x; T) = \text{const.}\ T^{2\nu} \tag{8}$$

where the constant depends on ν but not on T. We set $\langle x^2 \rangle_\nu = \langle x^2 \rangle_{cv}$ and obtain ν from plots of log $\langle x^2 \rangle_{cv}$ against log T. The values for the backbone (ν_b) and the side chain (ν_s) are given in Fig. 2*d* and *e*. Residues with small $\langle x^2 \rangle_{cv}$ generally have large values of ν, those with large $\langle x^2 \rangle_{cv}$ small values. Averaged over atoms with the same value of $\langle x^2 \rangle_{cv}$, the exponent ν satisfies the relation

$$\nu = \nu_0 \exp(-\xi \langle x^2 \rangle_{cv}) \tag{9}$$

where $\nu_0 = 4$, $\xi = 22$ Å^{-2} and with $\langle x^2 \rangle_{cv}$ measured at 250 K. Regions of the protein with small displacements behave like solids and have steep potential wells (V_5 in Fig. 1). In contrast, most parts with large $\langle x^2 \rangle_{cv}$ move in broad square wells (like $V_{0.05}$ in Fig. 1) and thus have many substates of about equal energy[33]. Only a few residues seem to have harmonic potentials, $\nu = 1/2$.

The behaviour of two residues, Arg 31 and Thr 67, is shown in Fig. 4. Figure 4*a* displays $\langle x^2 \rangle_{cv}$ for some atoms of the main chain and all non-hydrogen atoms of the side chains. For Arg 31, which lies on the outside of the protein, the displacements are large and increase with distance from the main chain. The displacements for Thr 67, which is in contact with the haem, are much smaller and show no clear dependence on distance. In Fig. 4*b*, $\langle x^2 \rangle_{cv}$ for some atoms of the two residues is plotted against temperature. The displacements of the atoms of the side chain of Arg 31 are essentially temperature independent ($\nu < 0.1$), whereas the atoms of Thr 67 show a pronounced temperature dependence ($\nu > 3$). The standard deviation of $\langle x^2 \rangle_{cv}$, 0.015 Å^2, is shown on some of the data points.

Figure 2*a* and *b* contains only one-fifth of our data at one temperature. Plotting all data would convey more information, but also obscure essential features. However, computer graphics provide a means of spatial representation of our results. Atoms are drawn as spheres with van der Waals radii and placed at their mean positions. Each atom is shaded according to the displacement $\langle x^2 \rangle_{cv}$. The protein is then cut in the desired plane, atoms exposed by the cut become visible, and structure and motion can then be observed at the same time. Figure 5 displays two such cuts through myoglobin at 250 K. A condensed core around the active centre, semi-liquid outer shells, and at least one pathway to the pocket on the distal side of the haem are apparent. The core can probably be likened to an aperiodic solid: the number of conformational substates per group of atoms is small, $\langle x^2 \rangle_{cv}$ is less than 0.04 Å^2 and the temperature coefficient ν is larger than 2. Residues in the semi-liquid regions have larger conformational displacements $\langle x^2 \rangle_{cv} \sim 0.04$–$0.25$ Å^2, and can probably assume many substates, and ν is generally less than 2. The term semi-liquid implies that the structure is liquid-like within volumes of a few Å^3; molecules may undergo brownian motion within the volumes accessible to them (micro-brownian motion) and the semi-liquid region may thus be very similar to glasses[34]. These features agree with the description used by McCammon, Gelin and Karplus ("fluid-like in that the local atom motions have a diffusional character")[15]. The displacement $\langle x^2 \rangle_{cv}$ increases nearly continuously from the inside to the protein surface.

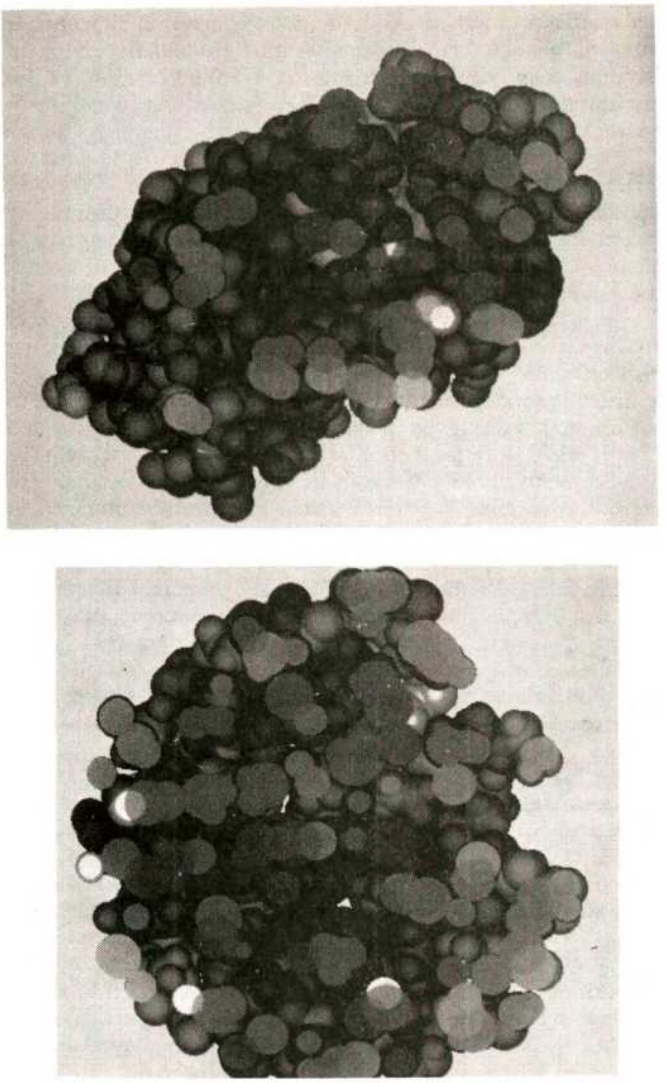

Fig. 5 Two slices through the 'dynamic' structure of myoglobin. Atoms are shown as spheres with van der Waals radii centred at their mean X-ray positions. Spheres interpenetrate when atoms are covalently bonded. The shading of each atom is proportional to the mean-square displacement $\langle x^2 \rangle_{cv}$ at 250 K; the heavier the shading of the atom, the smaller the value of $\langle x^2 \rangle_{cv}$. The upper cut is in a plane parallel to the haem plane and slightly towards the distal histidine side. The lower cut is at right angles to the haem plane and passes through residues 93 and 106; only the 'active site' area is shown. The haem plane is horizontal in the centre of the figure; Arg 45 is to the right.

Future prospects

Our results suggest that the extraction of $\langle x^2 \rangle$ from the intensity of the diffraction peaks should be carried out for non-isotropic distributions (assumption (1)) and for charge densities that are not gaussian (assumption (2))[35]. In protein structure refinement the standard method assumes correct bond lengths and bond angles, and no poor van der Waals contacts. The average structure, which fits the observed X-ray data best, will have apparent wrong bond lengths and angles and poor van der Waals contacts.

X-ray diffraction yields only information about the spatial distribution of protein motion. The temporal behaviour must be studied by other means, such as NMR, fluorescence relaxation, flash photolysis and molecular dynamics[36]. The results presen-

ted in Figs 2–5 may provide the maps to guide such work. As some of these other tools may be applied to solutions and single crystals, they may also answer the question of whether the dynamic properties of a protein are identical in a crystal and a solvent.

We thank Takashi Yonetani for the myoglobin single crystals, Fritz Parak for providing some of the crucial numbers, Richard Feldmann for creating Fig. 5, and Pierre Douzou for bringing us together. Among those who have helped us in preparing this paper are D. Beece, P. G. Debrunner, B. Gavish, E. Gratton, L. Jensen, M. Karplus, F. Parak, D. C. Phillips, L. Reinisch, F. M. Richards, A. Rich, L. B. Sorensen, W. M. Visscher, W. W. Webb, K. Wüthrich and K. T. Yue. H.F. has enjoyed the hospitality of the Aspen Center of Physics and the Los Alamos Scientific Laboratory. The work was partly supported by NSF grants PCM 76-01366 and PCM 78-08534 and by NIH grant GM 18051. G.A.P. is an Alfred P. Sloan Foundation Fellow, and thanks USPHS for a Research Career Development Award.

The patterns of atomic displacements in the crystals of hen and human lysozyme derived from independent crystallographic refinement are broadly similar. Analysis of the pattern indicates a close correlation with molecular structure, strongly suggestive of intramolecular motion. The active site of lysozyme is located in a region of high displacement. It is concluded that protein mobility may play a significant part in biological activity and that X-ray crystallography can contribute to its analysis.

THE distribution of electron density within a molecule, which is given by X-ray analysis of single crystals, can be used to determine two major pieces of information about the atoms making up the molecule. First, the mean positional coordinates of each atom can be obtained from the maxima in the distribution, and second, the mean square amplitude of displacement of each atom from its mean position can be derived from the rate at which the electron density falls off from the corresponding maximum. A quantitative estimate of the mean square displacement can be obtained from crystallographic refinement in reciprocal space in which the electron density of each atom is modelled by $f \exp(-Bs)$, where f is the scattering factor for the atom at rest, s is a reciprocal lattice vector, and B (often called the temperature factor) is related to the mean square amplitude of harmonic diplacement (U^2) by the expression $B = 8\pi^2 U^2$. If isotropic displacement is assumed, the B-factor has a single value; however, anisotropic displacement can be modelled by splitting B into six parameters whose values define the axial lengths and orientation of an ellipsoid of displacement.

Although analysis of B-factors is routinely used in the crystallography of small molecules[1], it is much less frequently applied to protein molecules, despite the possible significance[2–4] of knowledge of atomic displacements for the study of protein dynamics, and their role in biological activity. At least part of the reason for this is that there are several experimental difficulties in obtaining accurate B values, and theoretical problems in relating observed displacements to true atomic motion, which are exacerbated in the case of very large molecules like proteins. The most vexing of the theoretical problems arises because the X-ray measurements are averaged over time and, in effect, over crystal space. Consequently, there is no time component associated with the observed displacements, and this makes it impossible to distinguish directly between true atomic motion derived from vibrational and rotational modes, and static disorder caused by different molecules in the crystal adopting different conformations, or occupying different positions and orientations in the various unit cells. A possible way of distinguishing true atomic motion from static disorder is by analysis of X-ray intensities collected at different temperatures[5]. (See accompanying paper[6] for a discussion of this, and other approaches to the problem.)

At least two other problems at this level of significance must be considered before any attempt can be made to use B factors to describe protein dynamics. First, because the values of the B factors are determined largely from the variation of the X-ray

pattern with diffraction angle, the observed displacements are potentially very sensitive to systematic errors in the collection and correction of the X-ray measurements. Errors of this kind are particularly difficult to avoid when using large[7], liquid-containing, radiation-unstable[8] protein crystals. In addition, observable X-ray intensities from protein crystals are restricted to lower diffraction angles than those from most crystals of small molecules; this will therefore reduce the precision of the observed displacements. Second, the crystal packing may modify the atomic displacements as compared with those in free solution. Unlike small molecules, globular protein molecules are stabilised by the same weak forces that stabilise the crystals, and, although this factor may endow protein molecules with a richer variety of motions than small molecules, it may also increase the relative influence of the crystal environment on the actual displacements.

In this report we compare the displacements of the homologous hen and human lysozyme molecules, which crystallise in quite different space groups. Our results were derived from independent refinements of sets of X-ray intensities at different resolution, which were collected and corrected by different procedures. The close agreement of the displacements not only suggests that the effects of experimental error and crystal packing are not as serious as might be thought, but also that the pattern of displacements may represent a characteristic molecular property of biological significance.

Treatment of X-ray intensity data

The values of the B factors are derived from independent refinements of hen egg-white lysozyme (HEWL) at 2 Å resolution (D.E.P.G. and D.C.P., unpublished) and the homologous[9] human lysozyme (HL) at 1.5 Å resolution (P.J.A. and C.C.F.B., unpublished). The two enzymes crystallise in unrelated space groups, HEWL in $P4_32_12$ with $a = b = 79.1$ Å, $c = 37.9$ Å (ref. 10), and HL in $P2_12_12_1$ with $a = 57.1$ Å, $b = 61.0$ Å, $c = 32.9$ Å (ref. 14). In their respective unit cells the molecules are quite differently packed.

The collection and correction of the X-ray intensity data were carried out using different procedures. The X-ray intensities of HEWL[10] were collected in levels in reciprocal space on a linear diffractometer adapted to measure three reflections simultaneously[11]. More than half the reflections were measured four or more times and fewer than 5% only once. No crystal was used for longer than 20 h so that the unreduced data comprised ~30,000 measurements from 14 crystals. In contrast, the intensities of HL were measured on a computer-controlled five-circle diffractometer equipped to measure five reflections simultaneously[12]. The intensities were collected in shells in reciprocal space, each reflection being measured at least twice. Only one crystal was used for the complete data set of 50,000 reflections.

Data reduction and correction were also carried out by different methods: the net intensities of HEWL were obtained by the background–peak–background method, those of HL by profile fitting[13]. Radiation damage in HEWL was estimated from a common row of reflections measured before and after each level, and the correction was applied to each triplet level. In HL[14] it was estimated from a set of reference reflections monitored throughout the data run, and applied as a single correction to the whole data set. Absorption was corrected in HEWL by a two-dimensional[7], and in HL by a three-dimensional method[15].

Refinement of the HEWL structure was carried out by automated shifts estimated from difference syntheses[17], using the RS5D coordinates produced by the Diamond real-space refinement[16] as the starting point. Constraints on covalent bond lengths and angles, but not on non-bonded or hydrogen-bond interactions, were applied to the coordinates after one or more

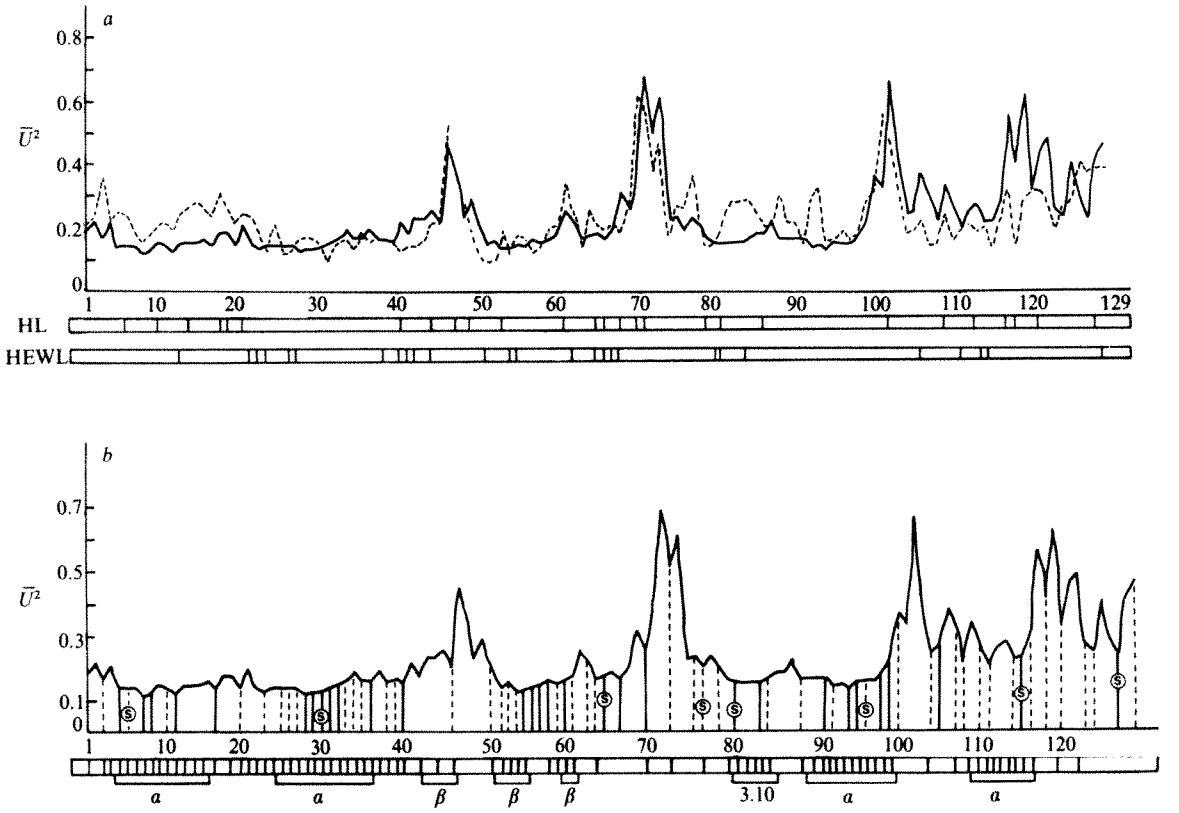

Fig. 1 *a*, A plot of mean main-chain $\overline{U^2}$ values against residue number for HL (full line) and HEWL (broken line). The numbering scheme is for HEWL; the additional residue in HL is inserted between residues 47 and 48. Residues involved in intermolecular contacts in the crystals of the two molecules are indicated in the lower rectangles. *b*, As *a* for HL. The full vertical lines indicate the location of internal residues in the lysozyme molecule, and the broken vertical lines residues lying in the molecular surface[24]. The residues involved in intramolecular hydrogen bonds are shown in the lower rectangle.

cycles of shifts. Because at 2 Å resolution there are only 9,600 structure amplitudes, only two B factors were used to describe each residue, one for the four main-chain atoms and the β-carbon, and another for the side-chain atoms beyond C^β. The refinement has not been completed but the R factor is currently 0.22 for all 9,600 terms using 1,001 protein atoms and some 250 water molecules. The initial stages of the HL refinement also used difference syntheses, but the later stages were mainly carried out using the constrained least-squares method of Hendrickson and Konnert[18]. Rather tight constraints were imposed on the covalent structure of the protein: covalent bond lengths were not allowed to vary by more than 0.01 Å. However, the weights of the constraints on non-bonded interactions and hydrogen bonds were reduced to the minimum values allowed by the Konnert programme (10^{-8} of the weight of the covalent constraints), and no constraints were imposed on the B factors at any point. At intervals during the least-squares refinement, a few cycles of difference map shifts were carried out to monitor the course of the least-squares refinement. The additional resolution available for HL allowed refinement of individual B factor for each atom. The current R factor for all 19,000 terms to 1.5 Å is 0.18 (≡0.17 at 2 Å resolution) using 1,026 protein atoms and 130 water molecules.

We know that the use of tight stereochemical constraints may not always be appropriate because of the effects of libration, first discussed by Cruickshank[33]. On the other hand, because constraints are used to compensate for the lack of true atomic resolution even at 1.5 Å, relaxation of the constraints to allow for libration would be expected to result in some degree of randomisation of the atomic positions elsewhere. Preliminary consideration of this complex problem suggests that the B values of atoms positioned incorrectly, through the application of inappropriate constraints or any other factor, will become anomalously high so as to maximise the overlap between the model and the real electron density.

Comparison of the displacements

Figure 1*a* shows a plot of the mean square displacement of the main-chain atoms of HEWL and HL against residue number. For HEWL, $\overline{U^2}$ has been obtained from the common B factor for the N, C^α, C', O and C^β atoms for each residue, and for HL it has been obtained by calculating the mean B value for the equivalent five atoms in each residue. It can be seen that, to a first approximation at least, the two plots have the same characteristics: a fairly constant background on which are superposed several peaks corresponding to residues 47, 70–73, and 101 and 102. Although there are some differences, particularly around residues 117–119 and 121 and 122, which in HL have greater displacements than in HEWL, the general agrement is good, as shown by the correlation coefficient of 0.61. The distribution of $\overline{U^2}$ is much smoother for HL, which almost certainly reflects the more accurate B factors obtained from the more complete refinement of higher resolution data. As each step in the collection, reduction and correction of the X-ray data from the two molecules has been carried out differently, it is most unlikely that the parallel variations in these curves represent merely the incorporation of systematic experimental error into the B values. Similarly, because the two enzymes are packed together in their respective crystal lattices in quite different ways, the observed variations in $\overline{U^2}$ cannot in the main be due to interactions in the crystal.

These considerations suggest that the parallel variation of the displacement curves represents some particular property of the HEWL and HL molecules themselves. As there are 51 side-chain substitutions and one additional residue in the HL molecule[19,20] as compared with HEWL, it seems probable that the main chain is the major determinant of the variation. We will now consider two major possibilities: (1) that the variation is a consequence of a rigid-body displacement or simple intramolecular displacement, and (2) that it corresponds to more complex intramolecular displacements. Broadly, these two possibilities can be investigated by determining whether the displacements are related to the shape of the molecule, or to its structure, respectively.

Analysis of main-chain displacements

Various models of possible overall intermolecular and intramolecular displacement of the averaged main-chain $\overline{U^2}$ values were examined. All the models that M.J.E.S., D.E.P.G. and D.C.P.[21] describe in their analysis of HEWL were considered for both molecules, and the salient results are summarised below. The best parameters to describe each model were found by a least-squares fit to the observed $\overline{U^2}$ values, and the quality of fit by a parameter R^2, expressed by

$$R^2 = \sum_{a=1}^{N} [(\overline{U^2}_a)_{obs} - (\overline{U^2}_a)_{calc}]^2 / \sum_{a=1}^{N} [(\overline{U^2}_a)_{obs} - \overline{U^2}_{mean}]^2$$

where

$$\overline{U^2}_{mean} = \sum_{a=1}^{N} (\overline{U^2}_a)_{obs}/N$$

and N is the number of residues. $R_2 = 0$ indicates total agreement and $R^2 = 1$ the worst possible agreement. The models described are as follows.

Model A: a rigid body mode, consisting of a uniform translational displacement together with independent librational displacements about three principal axes that intersect at the centroid (the 'TL' model of Cruickshank[22]).

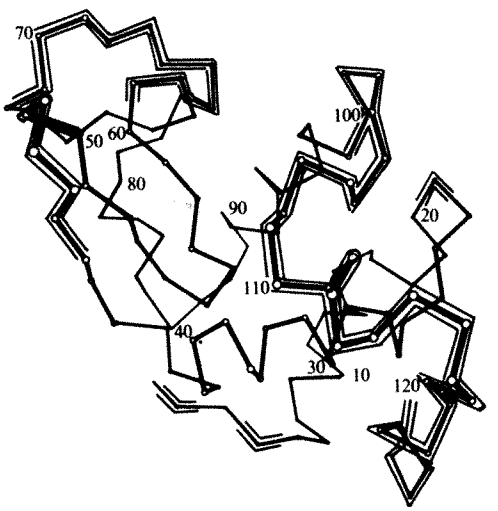

Fig. 3 A perspective drawing of the lysozyme molecule with the residues having displacement >0.2 Å^2, in HL outlined by the parallel lines. The active site cleft runs almost vertically down the front of the drawing.

Model B: a general 'breathing' mode, which is a reinterpretation of model A as intramolecular displacements consisting of a uniform component together with displacements that increase with distance from the molecular centroid, and have independent magnitudes along the three principal axes.

Model C: an intramolecular 'hinge bending' mode, in which displacements corresponding to a variation in the separation of the two lobes of the molecule that enclose the active site cleft, are superimposed on a uniform displacement. This mode is analogous to that studied by Karplus and coworkers[23] using energy calculations of molecular dynamics.

In neither molecule did hinge bending account for much of the variation [R^2(HEWL) = 0.79; R^2(HL) = 0.79], even though, as shown below, the lips of the active-site cleft correspond to regions of high displacement. Rigid-body displacement (model A) or the equivalent breathing mode (model B) gave better agreement [R^2(HEWL) = 0.54; R^2(HL) = 0.49]. The magnitudes of the libration or breathing for each molecule were significantly, and similarly, non-uniform along the three principal axes. However, the directions of the axes of principal displacement in HEWL and HL differed by 35°. Certain residues, including those marking the peaks in Fig. 1*a*, had markedly higher observed U^2 values than were accounted for by models A and B, and these residues probably have additional intramolecular displacements. Models A and B were therefore amended to include and determine the additional motion of each of these residues, increasing the agreement of these models to R^2(HEWL) = 0.17 and R^2(HL) = 0.13. Without anisotropic B values it is difficult to distinguish between the alternatives of rigid-body displacement and intramolecular breathing.

Given that even for the rigid-body model considerable allowance had to be made for intramolecular displacement, we have examined independently the case for intramolecular displacement by considering the relationship between the U^2 values and the molecular fold in terms of regular secondary structure and the relative exposure of the side chains[24]. Figure 1*b* shows the plot of this relationship, which indicates that segments of regular secondary structure, both α and β, correspond quite closely to the relatively smooth minima in the U^2 distribution. Closer examination reveals some correlation with the finer details of structure; for example, there are cyclic variations along the 4–16 and 108–116 helices that correspond to greater displacements of residues located on the exposed surface of these helices, and the most exposed strand, residues 42–46, of the small three-stranded β-sheet in lysozyme has a consistently higher displacement than the other two. There is also a good correlation between local minima in the U^2 plot with internal or surface residues. This is particularly striking in regions where there is little or no regular secondary structure; for example, in the C-terminal region, from residue 100 onwards, each downward trend in the sawtooth distribution of displacement corresponds to an internal or surface residue, and two of the deepest troughs correspond to the two disulphide links in this region, residues 115 and 127. Thus, the regions of high displacement correspond to main-chain segments that are not involved in regular secondary structure and whose side chains are external. These close correlations of displacement with structure reinforce the conclusion that we are observing a characteristic molecular property, and not some artefact of the crystallography.

If the regions of high displacement ($\overline{U^2} > 0.2$ Å^2) shown in Fig. 1*a* for HL are located on the folded lysozyme molecule (Fig. 3), it can be seen that most of them will lie on a continuous strip on the enzyme surface that begins at the exposed strand of the β-sheet, runs along to the 'top' of the molecule, down one side of the active-site cleft and along to the C-terminus. It is intriguing that this region of high displacement includes both lips of the active-site cleft[31], which is also the principal antigenic determinant of lysozyme[32], and also most of the main-chain segments which undergo conformational change when ligands are bound[31].

Analysis of side-chain displacements

Figure 2*b* shows a plot of $\overline{U^2}$ against r^2, where r is the distance from the molecular centroid for the side chains of human lysozyme. The striking feature of this plot is the clear discontinuity in the U^2 distribution at an r^2 value of about 180 Å^2: below this value the displacements are closely grouped between 0.1 and 0.3 Å^2, but above this value the displacements vary widely, with several displacements up to 1.25 Å^2 corresponding to the arbitrary allowed maximum for B factor of 100 Å^2. The lysozyme molecule is ellipsoidal, with dimensions of about 30 Å × 30 Å × 45 Å (ref. 10). Thus, the value of r at the discontinuity of about 14 Å corresponds quite closely to the minimum radius of the molecule. This shows that the internal residues, those with $r^2 < 180$ Å^2, are subject to quite small displacements of the same order as the main-chain displacement in this region (Fig. 2*a*), whereas those side chains with $r^2 >$ 180 Å, which are mostly external, have widely varying displacements, some of which are very large. To analyse the pattern of side-chain displacements more closely we have listed the mean difference between the side-chain and main-chain displacement for each type of amino acid residue (Table 1). With the exception of the smallest of the hydrophobic residues (Ala) all types of side chains are displaced more than their local main

Table 1 Incremental displacements of the side chains of human lysozyme

Type	No.	$\langle\Delta\overline{U^2}\rangle$	Type	No.	$\langle\Delta\overline{U^2}\rangle$
Ala	14	−0.006 ± 0.020	Ser	6	0.024 ± 0.052
Cys	8	0.008 ± 0.028	Thr	5	0.013 ± 0.055
Val	9	0.012 ± 0.057	Pro	2	0.145 ± 0.173
Ile	5	0.023 ± 0.019	Asp	8	0.152 ± 0.079
Leu	8	0.069 ± 0.043	Asn	10	0.208 ± 0.207
Met	2	0.051 ± 0.030	His	1	0.404
Phe	2	0.051 ± 0.046	Tyr	6	0.108 ± 0.157
Trp	5	0.049 ± 0.027	Glu	3	0,380 ± 0.351
			Gln	6	0.387 ± 0.280
			Lys	5	0.251 ± 0.230
			Arg	14	0.380 ± 0.276

$\langle\Delta\overline{U^2}\rangle = (\sum_{a=1}^{n}\langle\overline{U^2}_a\rangle$ side-chain atoms $-\langle\overline{U^2}_a\rangle$ main-chain atoms$)/n$, where n is the number of side chains of a given type. In the calculation the β-carbon is considered to be part of the main chain: relaxation of this condition is required to calculate the incremental displacement for alanines. The increase of the spread of the values with increasing $\langle\Delta\overline{U^2}\rangle$ shows that the side chains with largest incremental displacements also show the largest variations.

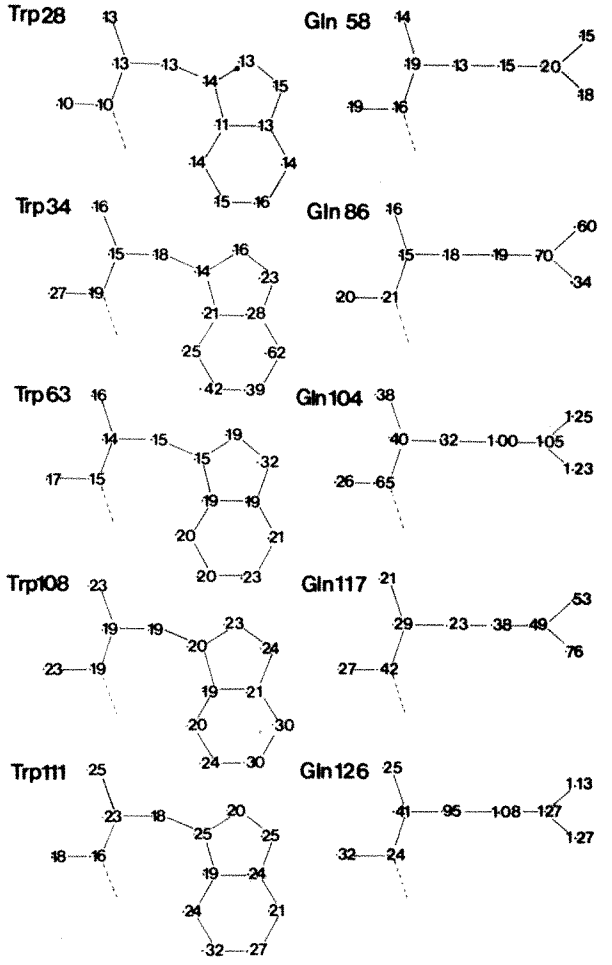

Fig. 4 The five tryptophan residues, and five of the six glutamine residues of human lysozyme showing the individual mean-square displacements of their atoms in Å^2. Trp 28 is the only residue of this group that is totally buried in the core of the molecule, and its atoms show consistently low displacements. In Trp 34, 108 and 111 it can be seen that the atoms of the six-membered part of the indole ring have larger displacements than the other atoms, consistent with some degreee of 'flapping' displacement about their α–β or β–γ bonds. In contrast to the tryptophan residues, the glutamine residues, which with the exception of Gln 58 are external, show increasingly large displacements along their length. Gln 58 lies in the surface of the enzyme with its amide group hydrogen bonded to the main chain, and the displacements of its atoms are lower and do not increase along the length of the side chain. The pattern of displacements in other types of side chain are fully consistent with these examples.

chains. The positive increment is quite small for all hydrophobic residues, but increases sharply with length for the hydrophilic side chains. This analysis reinforces the above conclusion, and suggests that the displacement of side chains is governed largely by their environment and their length, or perhaps, more precisely, by the number of bonds about which free rotation is possible. Figure 4 shows the atomic displacements of the tryptophan and glutamine residues. We have also made a preliminary analysis of anisotropic displacements of certain side chains. Figure 5 shows the results for Trp 63 which suggest that the indole ring of this residue undergoes greatest displacement in the plane of the ring.

Discussion

This study suggests that X-ray crystallography can be used to describe the atomic displacements in a protein molecule. Preliminary analyses indicate that the displacements must have an intramolecular component superimposed on either a rigid-body motion or a general breathing mode. The close correlation between the displacements and the molecular structure suggests that the observed pattern of displacements is characteristic of the lysozyme molecule. Possibly the most significant finding is that the lips of the active-site cleft, and the region of the enzyme that undergoes conformational change on ligand binding to the active site, are included in the regions that have the greatest displacements.

Unfortunately, the X-ray data described here do not allow us to interpret these displacements directly in terms of motion. There is, however, both theoretical and experimental evidence of intramolecular motion in proteins. Scheringer[25] has shown that even in molecules much smaller than lysozyme, the contribution of intramolecular motion increases with the number of atoms in the molecule. His analysis gives a rough estimate of the mean-square amplitude of intramolecular motion in lysozyme as 0.2 Å^2, which compares remarkably well with mean-square displacement amplitude of 0.23 Å^2 that we observe for the main-chain atoms of both HEWL and HL. A study of the dynamic motion of the pancreatic trypsin inhibitor[4] by energy calculations has estimated an r.m.s. displacement for all non-hydrogen atoms of 0.9 Å, the main chain moving less than the side chains. Nuclear magnetic resonance studies of HEWL in solution[26–28] have shown that Tyr and Phe residues 'flip' by 180° about their β–γ bonds; this requires considerable movement in neighbouring atoms and that external side chains undergo a rapid waving motion. Hydrogen–isotope exchange data for proteins have been interpreted as indicating breathing motions in proteins[29], and the similarity in the rates of hydrogen–tritium exchange of HEWL in solution and in the crystal[30] implies that the motion is not reduced by crystallisation.

This evidence of motion in proteins, which is consistent in a qualitative sense with our observations, suggests that it is reasonable to allocate some part of the observed displacement to molecular motion. However, there must be further investigation of methods, such as the analysis of the temperature dependence of the displacements, that may help in apportioning the relative contributions of static disorder and motion to the observed displacements. The analysis of the motion in terms of the contributions from rigid-body and intramolecular modes would be much improved if a complete set of anisotropic B factors could be calculated; this may be possible at 1.5 Å resolution or better. It is also evident that thermal diffuse scattering can be observed from proteins using synchrotron radiation (L. N. Johnson, personal communication), which could provide evidence of dominant libration axes[1]. The importance of anharmonic vibrations[21] might also be assessed, for example, by reformulation of the temperature factors in the manner proposed by Dawson[34] and Johnson[35]. Finally, in view of the location of some parts of the active site of lysozyme in regions of high displacement, if would be very interesting to discover the effect of binding substrate-like ligands on the pattern of displacements.

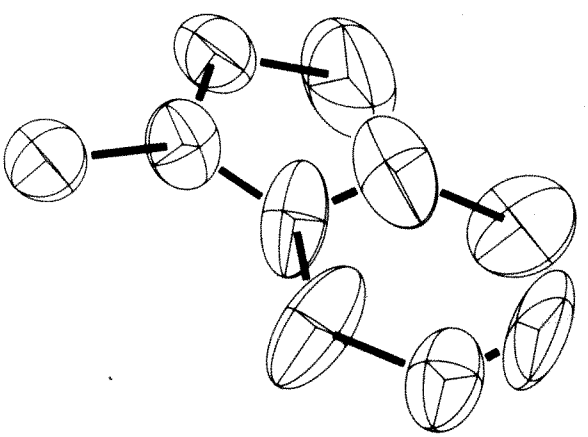

Fig. 5 A conventional drawing of the displacement ellipsoids of Trp 63 obtained from a preliminary analysis of anisotropic B values of the tryptophan residue of human lysozyme.

Soft X-ray emission from the vicinity of MV Lyr

EVIDENCE is presented for the existence of an X-ray source in the range 0.18–0.43 keV at a location consistent with the position of the 'nova-like' variable star MV Lyr. The source, designated H1901+43, was observed by the HEAO-1 A2 experiment[1] between 18 and 22 October 1977.

We have analysed data from the smallest field of view of the A2 experiment 0.18–2.5 keV detectors. This has dimensions of 1.55° FWHM in the scan direction (ecliptic latitude) and 3.1° FWHM in the perpendicular direction (ecliptic longitude). The total geometric area of the detector with this field of view is 175 cm^2. Figure 1 shows the 0.18–0.43 keV scan data in the vicinity of MV Lyr summed over the time interval specified above. A 5σ count excess above background is observed at the latitude of MV Lyr. The solid curve depicts the expected point source response of the detector collimator superposed on a parabolic background function. This combination has been fitted to the data in such a way as to minimise the χ^2 statistic, allowing the strength and position of the source to be free parameters, together with the background terms. Adding higher order terms to the background function does not improve the quality of the fit. The best fit source intensity in the 0.18–0.43 keV band is found to be 1.5 ± 0.3 counts s^{-1}.

No evidence is found for 0.5–2.5 keV emission from H1901+43. However, the data in this band are contaminated by emission from a second harder source, H1918+43, probably associated with the hard X-ray emitter 4U1919+44[2](2A1919+435[3]), which is separated from H1901+43 by ~1° in ecliptic latitude. We can conservatively adopt the measured flux of H1918+43 between 18 and 22 October, 1.0 counts s^{-1}, as an upper limit to 0.5–2.5 keV emission from H1901+43. The constraint thus imposed on the count ratio in the 0.18–0.43 and 0.5–2.5 keV bands limits the temperature of the H1901+43 source to be less than 1.2×10^7 K, assuming an optically thin bremsstrahlung spectrum. A lower limit to the temperature of $\sim 10^5$ K is implied by the low energy cut-off of the detector. Assuming a spectral temperature of 3×10^5 K, which is consistent with a detection in the 0.18–0.43 keV band only, the observed count rate corresponds to an energy flux of 4×10^{-12} erg cm^{-2} s^{-1} between 0.18 and 0.43 keV.

Figure 2 depicts the two-dimensional error box for H1901+43. The positional bounds in ecliptic latitude have been obtained by fitting the collimator response to the scan data, and correspond to a confidence level of 90%. The source location in ecliptic longitude is defined by the extent of the collimator in this direction (3.1° FWHM) and the daily motion of the satellite as it tracks the Sun. H1901+43 was observed in data taken on several consecutive days and must lie within the common area observed by the collimator on those days. The dimensions of the error box in this direction are therefore less than the full width at base of the collimator and define absolute limits on the position of the source in ecliptic longitude. The error boxes for the 2–10 keV sources 4U1919+46 and 2A1919+438 are also shown in Fig. 2. The positions of these medium energy sources are inconsistent with that of H1901+43.

It can be seen from Fig. 2 that MV Lyr is well contained within the error box of H1901+43. A cursory search revealed no other obvious candidates for the source of the X-ray emission. This, coupled with the fact that several other cataclysmic variables, notably AM Her[4], U Gem[5] and SS Cyg[6] have been found to emit soft X-ray radiation, leads us to suggest MV Lyr as a candidate for identification with H1901+43. Note, however, that the possibility of chance positional coincidence cannot be discounted because of the large positional uncertainty involved. MV Lyr was within the ±3.1° longitudinal extent of the detector collimator between 16 and 30 October. H1901+43 was detected in scan data summed between 18 and 22 October, when the mean distance of MV Lyr from the scan path was ~1°. If the identification with the star is correct, the failure to detect X-ray emission after 22 October may imply variability. This would not be surprising in view of the variable nature of the X-ray sources associated with other cataclysmic variables[4,5].

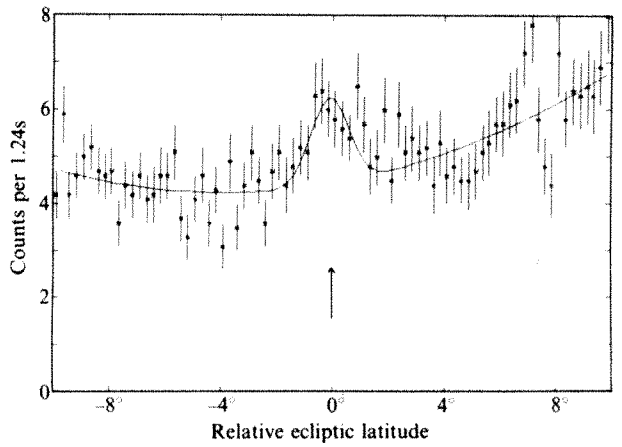

Fig. 1 Summed scan data in the 0.18–0.43 keV band plotted relative to the expected position of MV Lyr (arrow). The solid curve is the best fit collimator response superposed on a parabolic background function.

MV Lyr can be classed among the nova-like stars which have as their prototype UX UMa[7–9]. It exhibits rapid light variations[8,10] and a hydrogen emission spectrum which may be superposed on broad Balmer absorption[8,10–12]. There is evidence that MV Lyr is a binary system with an orbital period of ~2 h (ref. 11). The spectrum, luminosity and temporal characteristics of the UX UMa stars are similar to those of the dwarf novae at maximum light, and they may be essentially the same kind of system, but in an extended outburst[7–9]. Further to this suggestion, we note that if the proposed X-ray identification is correct, the ratio of soft X-ray to optical luminosity for MV Lyr is within a factor of two that observed from U Gem during outburst[5]. The range of absolute magnitude inferred for the UX UMa stars as a class ($3 \leqslant M_v \leqslant 6$)[7] together with the observed visual magnitude of MV Lyr[7], suggests that this star is at a distance of between ~300 pc and ~1,200 pc, corresponding to an X-ray luminosity range of $(4–60) \times 10^{31}$ erg s^{-1}. The distance of the star is consistent with its detection at ~1/4 keV given its relatively high galactic latitude ($b^{II} = 16°$).

The tentative identification of MV Lyr as a soft X-ray emitter may provide an important clue to the relationship between various types of cataclysmic variable stars. We note that the likely optical counterpart for the X-ray source 2A0526–328 may also be a non-erupting cataclysmic variable[13]. It will be important to seek confirmation of these results, and to search for X-ray emission from other stars in the UX UMa category.

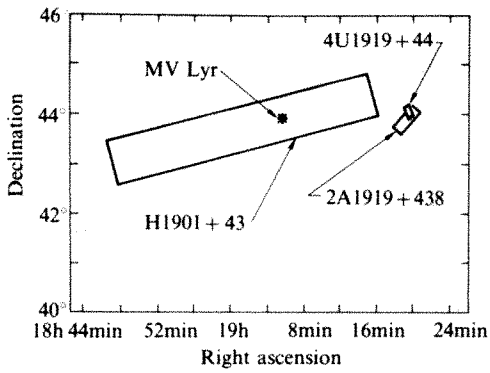

Fig. 2 Error box for H1901+43. The confidence level is 90% in the narrow (scan) direction. In the perpendicular direction, the positional uncertainty is defined by the dimensions of the collimator, and the time interval over which the source was detected.

Parity nonconservation and stellar collapse

ACCORDING to the current theory, the evolution of sufficiently massive stars leads eventually to gravitational instability and collapse. After thermonuclear burning has stopped, dense stellar cores become unstable and collapse to form neutron stars (pulsars) or black holes. In both cases energy of the order of $0.1\,Mc^2$ is released, mostly in the form of neutrinos and gravitational waves. As the radius of the core decreases, its magnetic field grows (magnetic flux is conserved) and can reach huge values of order 10^{12}–10^{13} G. Even greater azimuthal fields ($\sim 3 \times 10^{15}$ G) can be generated by differential rotation of the core[1]. It will be shown here that neutrino emission in the collapse is asymmetric, as a result of parity nonconservation in weak interactions. Neutrinos and antineutrinos are emitted preferentially in the direction parallel to the local magnetic field of the collapsing core.

The basic physical effect here is the generation of neutrino energy flux by magnetic fields in the presence of electrons (and positrons). The magnetic field polarises the electrons, and neutrinos scattering on electrons come off with their momenta correlated with the magnetic field. Clearly, this effect violates reflectional symmetry, as the energy flux is a polar vector and the magnetic field is an axial vector. The neutrino energy flux depends on the details of neutrino–electron scattering and its calculation requires a fully fledged transport theory. However, a crude estimation can be made if we take into account the following general features of electron–neutrino interaction. Neutrinos and antineutrinos are coupled to left-handed electrons and right-handed positrons more strongly than to right-handed electrons and left-handed positrons, the difference in the coupling constant being of the order of the coupling constant itself (assuming that electrons are relativistic, that is $T \geqslant 10^{10}$ K). The neutrino–electron cross-section is a rapidly growing function of energy, so that the probability of head-on collision is greater than that in the case of a neutrino running after an electron. Assuming for clarity that the magnetic field is directed upwards, it is easily seen that left-handed electrons and right-handed positrons move preferentially upwards, and thus neutrinos and antineutrinos moving down scatter more

0028–0836/79/330569—02$01.00

© Macmillan Journals Ltd 1979

frequently than those moving up. (In this order-of-magnitude estimation we disregard the motion of neutrinos in the transverse plane.) The ratio of the corresponding mean free times is of the order of $\tau_\downarrow/\tau_\uparrow \sim n_\uparrow/n_\downarrow$ where $n_\uparrow$ and $n_\downarrow$ are the densities of electrons with spin up and with spin down, respectively. If $\nu_\uparrow$ and $\nu_\downarrow$ are the densities of neutrinos moving up and moving down, respectively, then in a stationary flux $\nu_\uparrow/\tau_\uparrow \sim \nu_\downarrow/\tau_\downarrow$. Assuming for simplicity that the neutrino chemical potential is smaller than the temperature T, the neutrino momentum density $\mathbf{S}$ is of the order of $n_\nu T(n_\uparrow - n_\downarrow)/(n_\uparrow + n_\downarrow)$. Here $n_\nu = \nu_\uparrow + \nu_\downarrow \sim T^3$ is the total neutrino density and the system of units in which $c = \hbar = k = 1$ is used here. In the presence of scatterers other than electrons (such as neutrons or nuclei) the expression for $\mathbf{S}$ has to be multiplied by $\alpha \sim \tau_{\rm tot}/\tau_{\nu e}$, where $\tau_{\nu e}$ and $\tau_{\rm tot}$ are neutrino–electron and total neutrino mean free time, respectively. The ratio $(n_\uparrow - n_\downarrow)/(n_\uparrow + n_\downarrow)$ is of the order of $\mu B/\varepsilon$, where ε is the characteristic electron energy, $\varepsilon \sim T$ or $\varepsilon \sim \zeta_e$ (whichever is greater), $\mathbf{B}$ is the magnetic field, ζ_e is the chemical potential of electrons, and μ is the effective electron magnetic moment, $\mu = e/2\varepsilon$. (The latter equation follows from the expression[2] for electron energy levels in a constant magnetic field, $\varepsilon = (\varepsilon_0^2 \pm eB)^{1/2}$, where ε_0 is the spin-independent part of the energy.) The neutrino energy flux can now be written as

$$\mathbf{S} \sim \alpha n_\nu T \varepsilon^{-1} \mu \mathbf{B} \qquad (1)$$

This equation implies that the average momentum per neutrino is of the order of $\alpha\mu\mathbf{B}T/\varepsilon$. Note that neutrino and antineutrino currents in magnetic field have the same direction. A detailed derivation of equation (1) from the Boltzmann equation will be given elsewhere.

To estimate the role of parity-violating effects in stellar collapse, I shall use the results of numerical calculations for conventional supernovae models[3,4]. These calculations show that at the neutrino photosphere $T < \zeta_e \sim 13$ MeV, and thus $\varepsilon = \zeta_e \sim 13$ MeV. The neutrino transport is dominated by coherent scattering on nuclei, so that $\tau_{\rm tot} \sim 0.1\ \tau_{\nu e}$ and $\alpha \sim 0.1$. The total momentum carried away by neutrinos is of the order of

$$\mathbf{P} \sim \alpha N_\nu T \zeta_e^{-1} \mu \mathbf{B}_{\rm av} \sim \alpha E_\nu \zeta_e^{-1} \mu \mathbf{B}_{\rm av} \qquad (2)$$

where $N_\nu \sim E_\nu/T$ is the total number of emitted neutrinos, E_ν is the energy lost in the form of neutrinos, and $\mathbf{B}_{\rm av}$ is the magnetic field averaged over the neutrino photosphere (the quantities α, ζ_e and $\mathbf{B}_{\rm av}$ have also to be averaged over the whole period of intensive neutrino emission). The corresponding recoil velocity of the core is

$$\mathbf{v} \sim -\alpha\mu\mathbf{B}_{\rm av}E_\nu/M\zeta_e$$

For the characteristic values $B_{\rm av} \sim 5 \times 10^{12}$ G, $E_\nu/Mc^2 \sim 0.1$ we get $v \sim 5 \times 10^4$ cm s^{-1}. The actual velocities of pulsars are of the order of 10^7 cm s^{-1}. We see that the effect of asymmetric neutrino emission can account only for a small fraction of this value. The effect can be more important in collapse of magnetic stars where one can expect greater values of the magnetic field.

As already mentioned, the azimuthal magnetic field B_φ can be much greater than $B_{\rm av}$. Numerical calculations show[1] that the spatial distribution of the azimuthal field can be rather complicated. B_φ reaches its maximum value ($\sim 10^{15}$ G) in relatively small localised regions of the core. Neutrino fluxes generated by azithmuthal magnetic fields can have a role in a redistribution of the angular momentum of the collapsing core or of a hot neutron star. It can be shown that the angular momentum flux at distance r from the rotation axis is of the order of $\mathscr{L}_{\rm B} \sim \alpha n_\nu T \mu \zeta_e^{-1} l_\nu r \nabla B_\varphi$, where l_ν is the neutrino mean free path and it is assumed that the characteristic length scale of B_φ is smaller than r but greater than l_ν. An estimation shows that $\mathscr{L}_{\rm B}$ can be of a comparable magnitude to that of the neutrino angular momentum flux induced by rotation[5], $\mathscr{L}_{\rm R}$. However, the directions and thus the effects of the two fluxes are quite different. $\mathscr{L}_{\rm R}$ transports angular momentum from the inner to the outer parts of the core. $\mathscr{L}_{\rm B}$ tends to slow down the rotation in the regions of most intensive azimuthal field if the rotational velocity v_φ has the same sign as B_φ and tends to accelerate the rotation if $v_\varphi B_\varphi < 0$. If, for clarity the angular momentum of the core is directed upwards, then B_φ tends to have opposite signs in upper and lower hemispheres, and thus the flux $\mathscr{L}_{\rm B}$ develops an asymmetry in the angular velocity distribution.

I thank A. G. W. Cameron, A. E. Everett and D. Q. Lamb for helpful discussions.

Solar radio spectrum extended to 10 km wavelength

KNOWLEDGE of the range of solar radio burst flux densities is important for understanding the physical processes generating these bursts. However, past summaries of the solar radio spectrum[1,2], compiled from ground-based observations, have not extended to wavelengths much below 10m because the ionosphere of the Earth is opaque to longer wavelengths. Consequently, radio waves generated at altitudes above 5–10 solar radii in the outer corona can be observed only from above the ionosphere. The spectrum presented here covers wavelengths of 1 mm to 10 km; the observations between wavelengths of 100 m and 10 km were made by Earth satellites.

At hectometric and kilometric wavelengths thermal radiation from the Sun is typically five orders of magnitude weaker than the experiment threshold sensitivity, determined by local plasma noise and cosmic background noise. Nevertheless, satellites have detected hundreds of thousands of hectometric and kilometric solar radio bursts of nonthermal emission in the past decade. Type III solar radio bursts are by far the most common variety observed at these long wavelengths. According to our present knowledge[3], type III bursts are generated when energetic (10–100 keV) electrons are ejected from the Sun and travel outwards along open magnetic field lines. These energetic electrons excite emission at the second harmonic of the local solar wind electron plasma frequency. As the exciter electrons move away from the Sun into regions of lower density, the radiation occurs at progressively longer wavelengths and later times. Average type III burst emission wavelengths are 1 km at 0.3 AU and 5 km at 1 AU. A few type II bursts at wavelengths longer than 100 m have also been observed, occuring at both the fundamental and second harmonic of the plasma frequency in association with a propagating interplanetary shock[4,5].

Figure 1 includes long wavelength data from the Interplanetary Monitoring Platform IMP6 and the Radio Astronomy Explorer RAE1 Earth orbiters. Radio astronomy experiments on these satellites use long wire antennas, 91 m and 229 m respectively, connected to multi-channel radiometers in the frequency range of 25 kHz to 10 MHz. The IMP6 orbital altitude ranged from 2 to 33 Earth radii (the experimental arrangement has been described by Brown[6]). RAE1 operated in a circular orbit at an altitude of one Earth radius (its experiment systems have been discussed in detail elsewhere[7]).

Flux density measurements for very intense bursts are shown in Fig. 1. Smaller bursts are much more numerous. The distribution of burst maximum intensities at a given wavelength follows a power law, $n = A(\lambda)S^{-\beta}$, where n is the occurrence rate (bursts per day per unit flux density), S is the observed flux density, and $A(\lambda)$ is a constant for each wavelength. Observations demonstrate that $\beta = 1.5$ over a wavelength range of 0.1–300 m [8–10]. Accordingly, for a given wavelength, there are

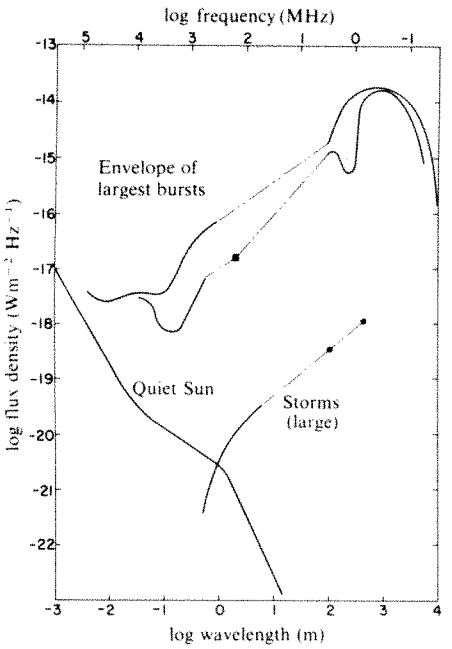

Fig. 1 Solar radio spectrum showing the envelope of flux levels reached by the largest reported bursts, one very large type III burst on 4 August 1972 (■), large noise storms, and the quiet Sun background. ●, RAE 1 measurements for a type III storm in August 1968.

approximately 3.2 times as many bursts with maximum flux density in the interval $S, S+\Delta S$ as in the interval $10S$, $10(S+\Delta S)$.

Evans *et al.*[11] reported RAE 1 measurements at 107 and 430 m for a type III storm in August 1968; these data are indicated in Fig. 1. A wide variety of spectra for many individual type III bursts observed by IMP 6 have been presented elsewhere[12,13]. Half of these bursts had spectral peaks occurring between 330 and 1,200 m; nearly all peaked within the 100 m–10 km observing range. The envelope of the largest long wavelength type III bursts, shown in Fig. 1, is derived from these IMP 6 data. This envelope should be considered as a lower limit for strongest bursts, because the IMP 6 observations cover only 500 days. The envelope of largest bursts at shorter wavelengths was assembled by Shimabukuro[2] from burst maxima observed between 1954 and 1972 by Badillo and Salcedo[14] and Castelli *et al.*[15]. Taken together, the envelopes of largest bursts indicate that the maximum observed flux density continues to increase with increasing wavelength up to a spectral peak near 500 m.

Figure 1 also contains the spectrum for a particularly intense burst associated with a large proton flare on 4 August 1972. This burst was reported by Castelli *et al.*[15] in the 3–60 cm range, by Solar Geophysical Data at 1.5 m and by me[12] in the 100 m–10 km range. Maximum flux density for the burst is observed between 330 and 1,500 m, wavelengths emitted at coronal levels of ~25–85 solar radii.

The quiet Sun spectrum is taken from Erickson *et al.*[16], Aubier *et al.*[17] and Linsky[18]. The spectrum for metric storms is from Wild *et al.*[1].

Solar radio burst flux densities have been observed far above quiet Sun flux levels, extending over seven decades of wavelength. These bursts are important indicators of solar activity. They are often associated with high-energy wave and particle emissions which influence the magnetosphere and upper atmosphere of the Earth. The long wavelength data contributed here show flux densities sometimes exceeding 10^{-14} Wm^{-2} Hz^{-1} in large bursts, with the most intense radio burst emission observed at wavelengths near 500 m and generated at heliocentric distances of 20–65 solar radii.

Chemical modification of a titanium (IV) oxide electrode to give stable dye sensitisation without a supersensitiser

SEMICONDUCTING electrodes stable in aqueous solution during the photoelectrochemical oxidation of water have generally been large-bandgap oxides, and their photosensitisation to visible light is of continuing interest[1]. In particular, n-type TiO_2 (rutile, with a bandgap of 3.0 eV) is a stable photoanode for the photoelectrolysis of water by uv light[2], and considerable effort has been devoted to its photosensitisation to sunlight[1]. One approach to photosensitisation is the use of a dye that, on excitation by visible light, transfers an electron to the conduction band of the solid and subsequently returns to its reduced ground state by the oxidation of water. The three major problems to be avoided are (1) irreversible degradative oxidation of the dye[3], (2) failure of the oxidised form of the dye to oxidise water, reduction being carried out by a supersensitiser, such as hydroquinone, that is consumed by the reaction[4,5], and (3) inefficient

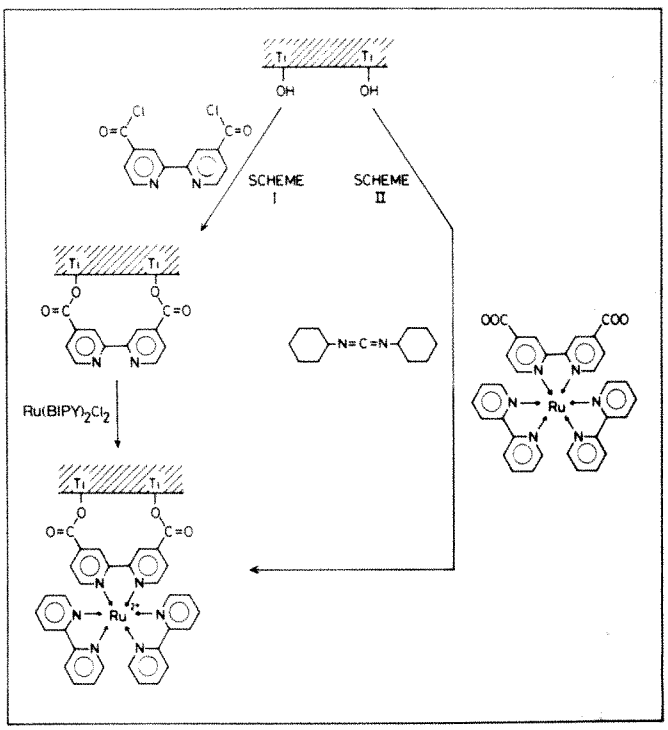

Fig. 1 Two reaction schemes for the derivatisation of TiO_2 with a monolayer of a $[Ru(BIPY)_3]^{2+}$ derivative.

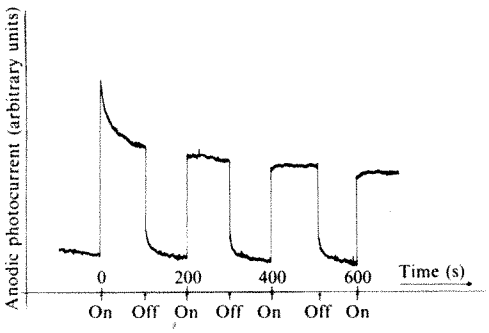

Fig. 2 Photocurrent–time characteristics for a derivatised TiO_2 electrode held at 1.2 V (versus SSE) and illuminated with light from a 150-W Xe lamp passing through a 450-nm interference filter. Arrows represent time of light switching on and off. Steady-state current was 70 nA cm^{-2}.

electron transfer from the dye to the solid[6]. To circumvent the first two of these problems, we have selected an inorganic complex as the dye, a derivative of $[Ru(BIPY)_3]^{2+}$ (BIPY = 2,2′-bipyridine). $[Ru(BIPY)_3]^{3+}$ is known to oxidise water in suitable *p*H conditions evolving about 80% of the theoretical yield of oxygen[7]. The last problem was avoided by chemically attaching the complex to the electrode surface, a procedure recently demonstrated for organic dyes (such as rhodamine-B) that require the use of a supersensitiser[4,5]. We report here that a single-crystal n-type TiO_2 electrode, chemically modified by the attachment of a monolayer of a derivative of $[Ru(BIPY)_3]^{2+}$, will produce significant anodic photocurrents when irradiated with visible light in the absence of a supersensitiser.

Two preparative routes (represented schematically in Fig. 1) were used to chemically modify single-crystal n-type TiO_2 electrodes. Both rely on the presence of electrode-surface sites that react like hydroxyl groups. Scheme I is a two-step process: derivatisation of the electrode surface with 2,2′-bipyridine-4,4′-di(carbonyl chloride), BPCC, followed by reaction with a solution of bis(2,2′-bipyridine)dichlororuthenium(II). Although BPCC has been prepared *in situ*[8], we report[9] its isolation and characterisation (by microanalysis, IR, NMR and mass spectrometry) for the first time. It was prepared by the reaction between 2,2′-bipyridine-4,4′-dicarboxylic acid, BPCA–H_2, and thionyl chloride. Scheme II represents a one-step derivatisation reaction between bis(2,2′-bipyridine)(2,2′-bipyridine-4,4′-dicarboxylate)ruthenium(II), $[Ru(BIPY)_2(BPCA)]$, and dicyclohexylcarbodiimide (DCC). Electrodes modified by both these routes showed similar electrochemical behaviour, and we assume that the product in each case is a monolayer of a stable ruthenium complex attached to the electrode by an ester linkage.

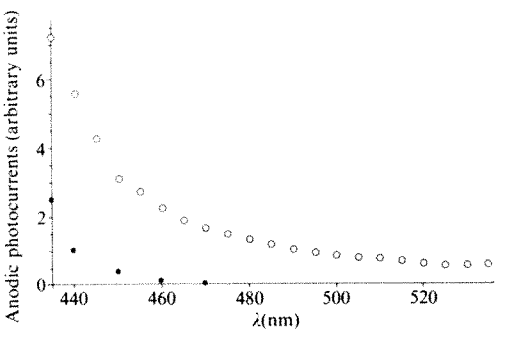

Fig. 3 Photocurrent–wavelength characteristics ('action spectrum') of a derivatised (○) and underivatised (●) TiO_2 electrode held at 1.0 V (versus SSE) (corrected for the lamp profile).

The photoelectrochemical responses of both modified and unmodified electrodes were studied with a.c. and d.c. techniques capable of detecting very small currents[10]. Their response to light from a xenon lamp filtered to remove all radiation with $\lambda < 450$ nm, a wavelength close to the absorption maximum of aqueous solutions of $[Ru(BIPY)_3]^{2+}$ (ref. 11), was measured. As the absorption edge of TiO_2 is 420 nm, any observed photocurrent cannot be due to an electron excitation across the semiconductor bandgap. Indeed, neither the unmodified electrodes nor those modified only by the first step of Scheme I (Fig. 1) showed any significant photoresponse, whereas the fully modified electrode exhibited the response illustrated in Fig. 2, which clearly indicates the critical role of the ruthenium(II) moiety. The d.c. photocurrent is anodic and falls initially to a steady value; it does not exhibit the slow-rise-time cathodic component that has been observed[10] with unmodified electrodes sensitised by $[Ru(BIPY)_3]^{2+}$ in solution. The steady-state current may be maintained for many hours, with no obvious signs of diminution. From these observations we conclude that light absorbed by the complex excites electrons into the conduction band of TiO_2, and the ruthenium(III) complex left on the surface is reduced back to ruthenium(II) by the capture of an electron from the solution. As no conventional supersensitiser is present in the aqueous electrolyte (0.5 M sulphuric acid) in contact with the electrode, we thus demonstrate the direct catalytic photo-oxidation of water with visible light. The oxidation occurs at a rate faster than that observed for the chemical oxidation of water by $[Ru(BIPY)_3]^{3+}$

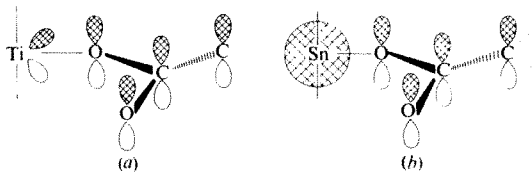

Fig. 4 Schematic representation of the orbitals of (*a*) esterified TiO_2 and (*b*) esterified SnO_2. Crosshatching represents positive lobes, no crosshatching represents negative lobes.

in homogeneous solution[12], as might be anticipated for a redox couple in a charged monolayer. Moreover, the initial decrease in photocurrent may be attributed to an oxidation of surface states at energies above the ruthenium(III) level in addition to the oxidation of water. These would remain empty in the dark at the +1.0 V bias [versus standard silver electrode (SSE), which itself is +0.22 V versus standard hydrogen electrode] of measurement, and indeed the steady-state photocurrent returns immediately after a dark-cycle. On the other hand, the surface-states would be refilled if the bias voltage is cycled to −0.1 V during the dark period, and in fact such a programme recovers the initial photocurrent when the light is again switched on.

An intriguing feature of the photoresponse of the modified electrode is the absence of a peak near 450 nm in the action spectrum (illustrated in Fig. 3). Such a peak would be expected if electron transfer followed dye excitation, and peaks characteristic of dye absorption have been observed with isostructural SnO_2 electrodes modified by both chemically attached rhodamine-B[4,5] and surfactant derivatives of $[Ru(BIPY)_3]^{2+}$ deposited by a Langmuir–Blodgett technique[12,13]. However, rhodamine-B attached to TiO_2 also gives a featureless action spectrum, similar to that shown in Fig. 3 (ref. 14), which suggests that, at TiO_2, the dye electron is excited directly into the conduction band. In TiO_2, the conduction band has a t_2-orbital parentage, which may bond strongly with the π^* system of the ruthenium–bipyridine complex through the ester linkage (see Fig 4); the 5s conduction band of SnO_2, on the other hand, is orthogonal to this π^* system. These observations suggest that the rate of electron transfer to the conduction band is much faster for TiO_2 than for SnO_2 modified electrodes. Experiments are in progress to further investigate and characterise these systems.

We thank the CEGB and SRC for financial support of this project. We also thank the CEGB for the award of a studentship (to S.A.) and a research fellowship at St Catherine's College (to K.R.S.), and the SRC for the award of studentships (to E.C.C., M.P.D-E. and R.D.W.). We are grateful to Dr H. J. Scheel for the gift of a single-crystal boule of TiO_2 of very high purity.

Odd and even numbered hydrogen ion clusters

Since the suggestion that hydrogen ion clusters of the type H_n^+ may be present in gaseous nebulae[1,2] and interstellar space[3,4] and the early experiments of Clampitt and Gowland[5], who discovered such clusters for $3 \leq n$ (odd) ≤ 99 in low temperature (3K) mass spectrometer experiments, it has sometimes been assumed that only odd-numbered clusters exist (ref. 6, and refs therein). There have been extensive studies in the past decade on the binding energy and the geometry of these ion-induced-dipole clusters. Massa *et al.*[7] have carried out *ab initio* calculations on H_n^+ for odd values of n ranging from 3 to 15. Weak binding energies of the order of 44 meV against dissociation according to

$$H_n^+ \rightarrow H_{n-2}^+ + H_2 \qquad 5 \leq n \text{ (odd)} \leq 15$$

were found. The geometrical shape of these clusters was calculated to be dominated by a triangular nucleating centre H_3^+ with the relatively high proton binding energy of 4 eV. Salmon and Poshusta[8] have conducted polarised-orbital valence-bond calculations on the ground state properties of H_5^+. Most recently, the molecular structure of H_3^+ has been experimentally determined by means of the beam-foil technique[9]. We describe here an ion-trap experiment in which we studied collisional processes of electrons with hydrogenic trapped ions of mass numbers, 1, 2, 3, 5, 7, 10, 14, and 20. Since these are the only ions observed, up to a mass limit of 40 AMU, there are serious implications for the assumption by some theoretical chemists that H_n^+ exists only for odd values of n.

The data were obtained in the hollow beam positive ion trap[10] (nonspecific in mass) with concentric electron beam collision facility; this has previously been used for the study of ionisation of atomic ions by electrons[11] and the temperature dependence of dissociative recombination and electron-impact dissociation of molecular ions[12,13].

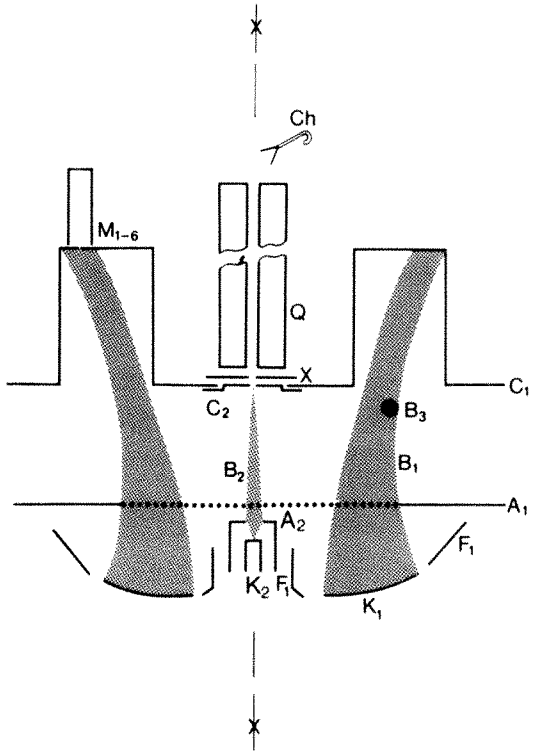

Fig. 1 Scale diagram of cylindrically symmetrical concentric electron beam device. Shaded beams: B_1, hollow electron beam; B_2, axial electron beam; B_3, molecular beam injected tangentially into hollow beam; K_1, toroidal cathode; K_2, rhenium strip filament; A_1, A_2, anodes; F_1, focusing electrode; C_1, hollow beam collector; C_2, axial beam collector; M_{1-6}, beam profile monitoring collectors; X, ion extraction electrode; Q, quadrupole mass spectrometer; Ch, channel electron multiplier.

The apparatus, shown in Fig. 1, consists of an indirectly-heated toroidal cathode which produces an intense electron beam; the potential configuration of the electron space charge produces a trap for positively-charged particles, the depth of which is of the order of 1 V. Advantage is taken of the capability of the hot nickel cathode to emit the species H_5^+, from which other hydrogen cluster species are derived by electron–ion and ion–ion collisions. These processes dominate within the hollow beam, which is collisionally pumped to an ultrahigh vacuum ($\sim 10^{-8}$ torr). A molecular beam is injected at B_3 (Fig. 1) whilst the hollow electron beam B_1 is in operation. A quadrupole mass spectrometer sampling system detects the resulting ionic products.

The hollow beam is operated at a perveance of 15 $\mu A\, V^{-\frac{3}{2}}$, with anode potentials V_{HB}, as shown in Fig. 2. It can safely be assumed that mass numbers 1, 2 and 3 correspond to the well-known H^+, H_2^+, and H_3^+ species. The definitive evidence of the assignment of mass 5 as H_5^+ is its dissociation[13] by axial beam electron impact into $H_3^+ + H_2$ and also $H^+ + 2H_2$. An upper limit of 10^{-13} A can be placed on mass 4 ion current so that the well-known HeH^+ can be ruled out. Alternative assignments for the other mass numbers might be possible: HF^+, 20; N^+, 14; Li^+, N^{2+}, 7; B^+, 10; but each presents difficulties such as the absence of N_2^+, 28; F^+, 19; Li^+, 6, or boron halide ions. In view of the absence of any other ion species in the trap (up to a mass limit of 40 AMU), the most likely conclusion is that all the ions in the trap are hydrogenic.

The intensities of ions of mass numbers 2, 3, 5, 7, 10, 14, and 20 are found to be independent of gas pressure over the range 10^{-8} to 10^{-5} torr, with slight increase in intensities in the region between 1×10^{-5} and 6×10^{-5} torr. The intensity of H^+ rises from 5×10^{-11} A at 2×10^{-7} torr to 1×10^{-7} A at 10^{-4} torr.

These cluster ions have been detected for the first time at laboratory temperatures because the hollow beam trap with surface-emitted H_5^+ ions successfully creates a situation in which

0028-0836/79/330573—02$01.00

© Macmillan Journals Ltd 1979

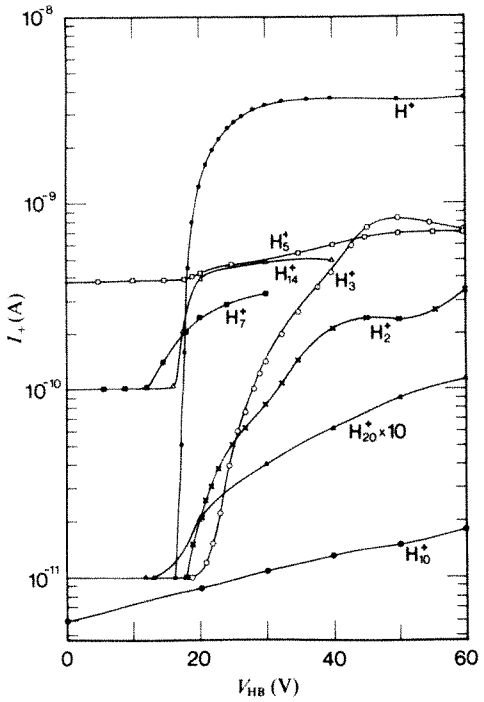

Fig. 2 Observed abundances of hydrogen ion clusters as functions of hollow beam energy V_{HB}.

ion–neutral collisions, which would destroy clusters and complexes, contribute only marginally. It can be speculated that ion–ion collisions of two types are responsible for cluster formation in our device. First, there is the possibility of three-body collisions in which the third body is an electron:

$$H_5^+ + H_5^+ + e \rightarrow H_{10}^+$$

H_5^+ is released from the nickel cathode surface, and is therefore independent of gas pressure and only marginally dependent on V_{HB}; therefore, if this process dominates H_{10}^+ should exhibit similar behaviour. The data in Fig. 2 indicate that H_{10}^+ does indeed persist at the lowest hollow-beam anode voltage. Similar arguments can be applied to the reaction:

$$H_{10}^+ + H_{10}^+ + e \rightarrow H_{20}^+$$

Second, it is possible that the observed ions are produced in the following types of process:

$$H_5^+ + H_5^+ \rightarrow H_7^+ + H_3^+$$
$$H_5^+ + H_7^+ \rightarrow H_{10}^+ + H_2^+$$
$$H_5^+ + H_3^+ \rightarrow H_7^+ + H^+$$
$$H_5^+ + H_{10}^+ \rightarrow H_{14}^+ + H^+$$

But why should odd-numbered clusters persist only up to $n = 7$, H_9^+ not being observed, although H_{10}^+ is stable? Conceivably in the low n odd-numbered clusters a proton orbits about H_2 molecules arranged orthogonally in one, two or three dimensions, so that a further extension of this principle beyond H_7^+ would not be possible.

No quantitative discussion of the cluster formation processes can be presented at this stage, but our data do indicate the need for theoretical chemists to initiate investigations of the hitherto unexplored problem of even-numbered H_n^+ clusters.

Processes controlling the stanol/stenol ratio in Black Sea seawater and sediments

STEROIDAL ALCOHOLS[1–10], ketones[11] and hydrocarbons[12,13] have been used as tracers for the transformation processes of biogenic organic matter in Recent sediments. Several of these studies have been concerned with one of the sedimentary transformation reactions of steroidal alcohols, the reduction of stenols to stanols. However, little attention has been directed towards the role of the overlying water column in controlling sedimentary stenol/stanol distributions. The input of stanols from surface-water organisms coupled with relatively different degradation rates of stenols and stanols[9,14] could also contribute to observed sediment distributions. To evaluate further the relative importance of these processes in controlling stanol/stenol distributions in anoxic water and surface sediments, we undertook a cruise to the Black Sea. Because water below 125 m is anoxic in the two central 2,000-m basins of the Black Sea, it is an ideal environment for observing any microbially or chemically mediated reduction reactions in the water column or surface sediments[15,16]. In addition, since the surface sediments are anoxic, the effects of macrobenthos on these reactions are minimal. Indeed, sterol transformation reactions have been postulated to be microbially mediated in sediments[1,2,7–9,11,13], and in seawater[17]. However, very few, if any, bacteria are thought to biosynthesise desmethyl stenols[17,18]. If stenol reduction reactions are chemically mediated, they should also be observed in this highly reducing (low E_H) environment. We discuss here the major processes controlling a specific transformation reaction (stenol to stanol conversion) of a class of biogenic organic compounds. These conclusions are based on results obtained by sampling both the sediments and the overlying water column from two stations in the Black Sea.

Seawater and sediment samples were collected on RV Chain Cruise 120, Leg 1 in April 1975. Core 7 was taken at hydrostation 1355, 42°50.0′ N, 33°00.0′ E, Core 23 was taken at 43°00.0′ N, 34°00.0′ E and hydrostation 1356 was taken at 42°41.3′ N, 30°65.5′ E. The procedure for collection of the water samples[17] and cores[19] and the interpretation of the hydrographic data[17] are reported elsewhere. The presence of high concentrations of hydrogen sulphide as well as the absence of dissolved oxygen in the sediments and within the anoxic zone of the water column restrict life primarily to various species of microorganisms[15,16]. Investigation of Recent sediments near Station 1355 has shown this environment to be of uniform deposition[20]. The sediment analysed contained approximately 4 cm of a loose black floc above a grey unconsolidated organic-rich material. Karl[16] found using scanning electron microscopy that the sediment contained coccoliths in various stages of dissolution and occasional diatom frustule fragments. In addition to these calcareous and siliceous detrital fragments, he observed many colonies of bacteria. A more detailed description of the sediment is published elsewhere[19]. The methods for the extraction, isolation, and quantification of the sterols are given in detail for seawater by R.B.G. and F.H.[17], and for sediments by C.L. *et al.*[5,6]. Structural assignments were based on high-resolution glass-capillary gas-chromatographic retention times of authentic sterol acetates in conjunction with glass capillary gas chromatography-mass spectrometry as described earlier[6,17].

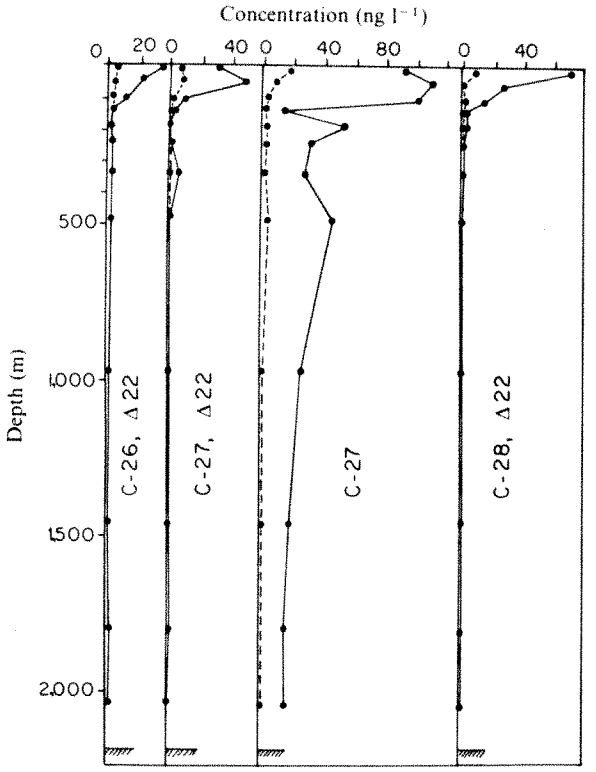

Fig. 1 Concentrations for four stanol (dashed lines), stenol (solid lines) pairs (I, II; III, IV; V, VI; VII, VIII) as a function of depth in the water column from Station 1355. See text for systematic names.

Sixteen stanols and stenols were resolved in the surface water samples from Stations 1355 and 1356 (ref. 17). Over 30 stenols were found in the surface sediments from Cores 7 and 23 (ref. 19). However, for the purpose of this report, we will limit our discussion to four clearly separable stanol/stenol pairs for both the seawater and sediment samples: 24-nor-5α-cholest-22-en-3β-ol(I)/24-norcholesta-5,22-dien-3β-ol(II); 5α-cholest-22(E)-en-3β-ol(III)/cholesta-5,22(E)-dien-3β-ol(IV); 5α-cholestan-3β-ol(V)/cholest-5-en-3β-ol(VI); and 24-methyl- 5α-cholest-22-en-3β-ol-(VII) / 24-methylcholesta-5,22-dien- 3β-ol(VIII). The concentrations of these stanol/stenol pairs as a function of depth in the water column for Station 1355 are shown in Fig. 1. Cholest-5-en-3β-ol and 5α-cholestan-3β-ol are the only sterols detected above blank levels in waters deeper than the O_2/H_2S interface (located at 110–130 m). Similar results were found for two other stations in the Black Sea[17]. Although stenol Δ5 bonds can be reduced chemically and microbiologically to both 5α and 5β stanols, only the 5α isomer of cholestanol was detected. In the upper 100 m of the water column, all eight sterols were found in concentrations ranging from 5 to 93 ng l^{-1}. The surface water stanol/stenol ratios for compounds I–VIII are 0.15, 0.16, 0.18 and 0.10 for the I/II, III/IV, V/VI, VII/VIII pairs respectively. These four sterol pairs were also found at the four depths sampled from Core 23 (Fig. 2) and the two depths sampled from Core 7. The 0–4-cm stanol/stenol ratios for the four respective pairs were found to be 0.28, 0.42, 1.17 and 0.45 for Core 23.

Since there is no evidence for sediment transport by turbidity currents at these locations and benthic sterol production is unlikely in the strongly anoxic water and sediments, the sedimentary sterols we observed were probably deposited by transport on large particles originating in the oxic zone but not captured by our seawater samplers. Recent studies using large-volume *in-situ* filtration systems[21], and moored[22,23] and free-floating[24] sediment traps indicate that the percentage of surface productivity rapidly reaching the sea floor directly below is much higher than previously thought. The large particles being transported potentially contain labile organic compounds since they reach the sea floor in a relatively short time (days).

The stanol/stenol ratio for the four corresponding pairs in the surface waters range from 0.10 to 0.18 (Fig. 1). These values are lower than those reported from surface sediments[2,7,10]. They probably reflect the input from stanol-containing organisms (jellyfish[25], red algae[26], echinoderms[27] and sponge[18]) since the bacterial conversion of stenol to stanol would be expected to be slow in the oxic surface waters[9,14]. From these comparatively high surface values, the concentrations of all the stanols decrease quickly with depth (faster than the corresponding stenols) to values near zero at the O_2/H_2S interface.

All of the stanol concentrations in the deep anoxic waters are below 5 ng l^{-1}. The only stanol/stenol pair that can be observed from the surface to the deep anoxic waters is the 5α-cholestan-3β-ol/cholest-5-en-3β-ol pair (Fig. 3). The ratio drops from surface values of 0.15–0.20 to a ratio of about 0.05 below 100 m. The high value at 140 m depth from Station 1355 is due to an extremely low cholest-5-en-3β-ol concentration rather than to an increase in 5α-cholestan-3β-ol (see Fig. 1). These results clearly show that no major chemical or microbial stenol → stanol conversion is occurring despite the highly favourable conditions at the interface and in the deep anoxic waters. The fact that the inflections of the stenol depth profiles are not mirrored by the corresponding stanol profiles[17] (Fig. 1) also indicates very strongly that the stanol/stenol ratio in the oxic zone (upper 100 m) is primarily determined by varying inputs from specific source organisms.

Sediment ratios are quite different than those in the water column. In both Cores 7 and 23 the stanol/stenol ratio is 1.18, decreasing to about 1.0 with depth. Several processes may be responsible for this large difference between seawater and sediment ratios. First, as mentioned above, large particles probably transport sterols from the surface waters to the sediment surface. Stenol → stanol conversion could take place as these large particles transit to the sea floor. However, this conversion was not observed on the small particles collected by our water samplers. Since the small particles have a longer time for reaction due to their longer residence time in the water column, it is unlikely that this conversion occurs on the large particles. This reasoning assumes that the organic and microbiological compositions on the large particles are the same as on the small particles. This may not be true since the larger particles will have had much less time to degrade in the water column and may be a hormonal or more nutritional substrate. Plankton and other surface organisms are sources of the large particles. However, they usually do not contain more than 10% stanols relative to stenols[8,9]. On the other hand, faecal pellets produced by these organisms are another source of large particulate matter[21,22,24], and may contain larger quantities of stanols formed by gut bacterial activity.

A second potential process for the increase in the stanol/stenol ratio in the surface sediments is selective degradation of stenols relative to stanols at the sediment/water interface. Enough stanols are produced in the surface waters to account for those we observed in the 0–4-cm sediment layer[9,28] which represents about 500 years' accumulation[19,20]. A selective degradation process is probably not occurring for two reasons.

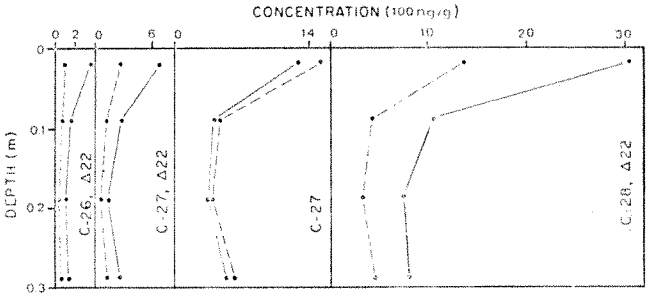

Fig. 2 Concentrations for four stanol (dashed lines), stenol (solid lines) pairs (I, II; III, IV; V, VI; VII, VIII) as a function of depth for Core 23. See text for systematic names.

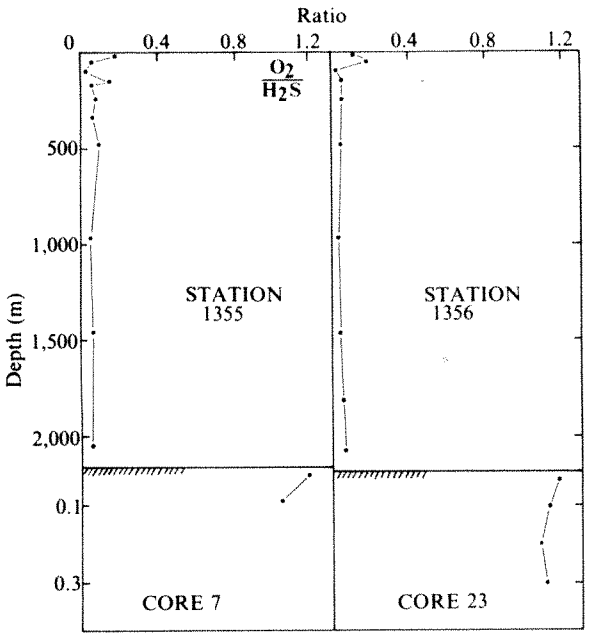

Fig. 3 Ratio of 5α-cholestan-3β-ol to cholest-5-en-3β-ol as a function of depth in the water column from Stations 1355 and 1356 and in Cores 7 and 23.

First, although stenols degrade faster than stanols in oxic lacustrine sediments, and the stenol → stanol conversion is slow, the case in microbially active anoxic sediments is different. It seems that stenol degradation is suppressed and the reduction of stenols to stanols occurs rapidly, causing a marked increase in the stanol/stenol ratio with depth[1,2,9,14]. Although this increase was observed in the surface sediments of the Black Sea, an increase with depth in the core was not found. However, the distribution of bacteria with depth and the sedimentation rate in the Black Sea can be expected to be quite different from those of lacustrine environments[1,7,16]. Second, if stenols were selectively being degraded relative to stanols, we might have expected the 5α-Δ22 stanols to degrade faster than 5α-cholestan-3β-ol. This does not appear to be the case, as shown in Figs 1 and 2. 5α-cholestan-3β-ol(V) is over twice the concentration of 24-methyl-5α-cholest-22-en-3β-ol(VII) in the surface waters. However, the concentration of VII is about equal to V in the surface sediment. The same argument applies for the stability of I and III relative to V.

The third possible process controlling stanol/stenol ratios in the surface sediments is direct stenol → stanol conversion at the sediment/water interface. Since microbiological hydrogenation of stenols is well known[29-31], this pathway has been postulated as a major source of stanols in anoxic lacustrine sediments[1,2,9,14]. The Black Sea sediments in this study have high microbial biomass and activity[16]. Hence, microbial transformation is the most likely control of stanol/stenol distributions in Black Sea surface sediments. However, input from large particles produced in the overlying water cannot be ruled out as a source of stanols. It is clear that in order to define the role large particles have in controlling surface sediment stanol/stenol distributions, sediment trap data is needed. We hope to collect such data in this most interesting anoxic environment in the near future.

Analysis of aliphatic and aromatic hydrocarbons in Antarctic marine sediment layers

THE presence of both paraffinic and polycyclic aromatic hydrocarbons (PAH) in sediments and soils from the Northern Hemisphere has been well documented[1-5]. Paraffinic hydrocarbons are generally assumed to be derived predominantly from land plants[6] but the sources of PAH are still uncertain[7]. However, the general consensus seems to be that they are from the fallout of airborne combustion products[3]. Industrialised areas have higher PAH loadings[5] whilst dated cores from areas with a history of increasing industrialisation show a concomitant increase in total PAH loads but no great change in the relative proportions of individual components. Considerable interest is also vested in the fate of hydrocarbons once deposited in sediments[6]. With mineral resources being depleted in more accessible areas, those of remote regions (including polar ones) are being considered. But little is yet known of the effects that near-zero temperatures may have on the rate of biochemical or chemical alteration of hydrocarbons such as those found in petroleum. We report here our attempts to test the 'combustion source hypothesis' and to investigate the fate of hydrocarbons in sediments from a remote sub-Antarctic island with a well-documented history of localised industrial pollution[8] spanning the period 1904–65. Only very minor local inputs of pollutant hydrocarbons are likely to have occurred on either side of these dates.

South Georgia (54 °S, 37 °W) became an important seal hunting ground during the first half of the nineteenth century. But with the virtual extinction of the local seals it was then little used until 1904, when a whale processing factory was built at King Edward Cove. Thereafter, fossil fuels (first coal and then, increasingly from about 1925, fuel oil) were transported to the factory to fire cookers and catchers. Fossil fuel contamination of the bay occurred especially when the tanks of the transporters were cleaned before reloading with whale oil. In addition, large quantities of organic material entered the bay as a result of

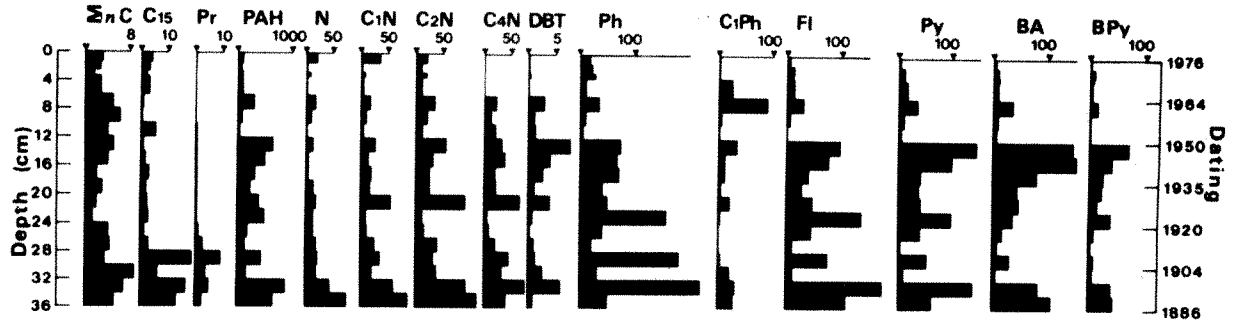

Fig. 1 Depth distribution of selected hydrocarbons in a marine sediment core from South Georgia (units are ng per g dry wt except for *n*-C and Pr (μg per g) and C_{15} (% of Σ*n*-C)). For abbreviations see Table 1.

processing the whales, most markedly before 1916 when only the blubber was utilised. The factory closed in 1965 and the site subsequently returned to light use, with a small scientific station being visited by occasional research and fishing vessels.

In 1976, divers collected cores from 18 m in the deepest part of the bay. Sections of a 2.2-cm diameter, 36-cm long core were extracted[9] and the alkane and PAH fractions isolated according to the method of Giger and Schaffner[10]. The quantitative alkane data were obtained by glass capillary GC[11]. Analyses of the PAHs were also performed on a glass capillary column but used a mass spectrometer, operated in the multiple ion mode, as a detector[11]. Identifications are based primarily on retention indices with random peaks scanned to confirm identities. A minimum of two injections of a standard mixture were made daily to confirm both retention time and spectrometer response. The parent ion was used for quantitation on all components except for the C1 and C2 substituted naphthalenes for which the M-1 and M-15 ions respectively were used.

The sediment core results are shown in Fig. 1 and the South Georgia whale oil (grade 2) and fuel oil (from abandoned storage tanks) data are given in Table 1. Figure 1 also shows a putative dating based on inferences made from the hydrocarbon and organic carbon profiles of the cores and from sedimentation experiments[12]. The estimate of the 1975–76 annual sedimentation rate based on sediment trap data agreed well with the implications of assuming that the unusual carbon profile reflected the increased organic input to the sediment during the whaling years. As this input of waste may have altered the sediment accumulation rate it is not easy to state the reliability of the precise dating between 1904 and 1965. However, all the available evidence seems to be consistent with the conclusion that the sediment at 30 cm depth (in 1976) was laid down in 1904 and that the average annual sedimentation rate thereafter was of the order of 2.8×10^3 g dry wt m^{-2}.

Present evidence suggests bioturbation could effectively backdate any dating by about 10 yr (any material layed down in 1 yr would be mixed with sediment laid down up to 10 yr previously). The macrobenthic fauna in the area[13] consists predominantly of burrowing polychaetes in the upper 2–4 cm aerobic layers. However, organic inputs from the whaling operations may have either altered the benthic fauna so as to increase bioturbation or reduce it and so decrease such mixing. Evidence from other areas subjected to massive organic pollution suggest the macrofauna would have been eliminated[14,15] so a large dating error due to macrobenthic activity between 1904 and 1965 is unlikely. Nevertheless, it is still possible that a persistent meiofaunal population could have survived to cause some mixing[16].

The upper sections of the core can be considered free of local pollution: most of the aliphatic components are entirely consistent with their being locally derived, from marine organisms and land plants[17]. However, as biogenic PAH synthesis is considered unlikely[18], the aromatic components would seem to be the result of a world-wide dissemination of natural or anthropogenic combustion effluents and/or petroleum. The low ratio of parent-to-alkylated phenanthrenes effectively rules out petroleum as a source, petroleum being low in unsubstituted species. This leaves combustion products from continental land masses as the prime source, as evidenced by the roughly equal proportions of fluoranthene to pyrene and the predominance of parent tricyclic over alkylated tricyclics[3]. Thus, the results from South Georgia support the hypothesis that sedimentary PAH are combustion derived.

The mean PAH concentration in the top 3.5 cm of the King Edward Cove mud (100 parts per 10^9 (p.p.b.) dry wt) was only eight times less than that found in the fine sands of Buzzards Bay[7], a shallow (17 m) site near the heavily industrialised northeastern seaboard of the US and just slightly less than the 160 p.p.b. figure for the (presumably) finer grained surficial sediments at 130 m depth 94 km west of Boston (Massachusetts)[4]. Therefore, despite the fact that PAH concentration is a function of sediment type as well as relative input, the concentrations found at South Georgia still seem to be surprisingly high for such an isolated location, indicating that global contamination reaches even remote parts of the world in relatively undiminished quantities.

The apparent presence of small amounts of PAH in the whale oil deserves comment. Table 1 shows that the relative proportions of the component PAHs bear a similarity to those of the fuel oil so that it seems that the whale oil probably became contaminated by petroleum at some stage.

Anthropogenic combustion of fossil fuels has been continuously increasing during this century[7], so that the greater hydrocarbon concentrations deeper in this core could only have resulted from the local industry. Indeed, the abrupt increase in many components at the 6–8 cm depth seems to coincide with the cessation of industrial activity. The obvious discontinuities in both amounts and distribution must reflect local contamination

Table 1 Hydrocarbon composition of whale oil and fuel oil from South Georgia

Component	Whale oil	Fuel oil
Total *n*-alkanes C_{15}–C_{33} (Σ*n*-C) (μg per g)	8.9	4.9×10^4
Normal pentadecane (C_{15}) (% of Σ*n*-C)	59.6	8.1
Pristane (Pr) (μg per g)	322.7	1550.9
Total identified PAHs (ng per g)	86.2	3.3×10^6
Naphthalene (N) (ng per g)	12.4	0.2×10^6
Methylnaphthalene (C1N) (ng per g)	14.3	0.7×10^6
Dimethylnaphthalene (C2N) (ng per g)	17.0	2.2×10^6
Tetramethylnaphthalene (C4N) (ng per g)	ND	0.4×10^6
Dibenzthiophene (DBT) (ng per g)	2.0	9.6×10^4
Phenanthrene (Ph) (ng per g)	5.8	5.5×10^4
Methylphenanthrene/anthracene (C1Ph) (ng per g)	26.1	10.8×10^4
Fluoranthene (F1) (ng per g)	0.6	ND
Pyrene (Py) (ng per g)	1.8	0.5×10^4
Benzanthracene/phenanthrene (BA) (ng per g)	6.6	3.6×10^4
Benzo(*a*)pyrene (BPy) (ng per g)	1.6	0.4×10^4

ND, not detected.

as all other sources should in principle give relatively homogeneous distributions. These discontinuities further imply that neither diffusion nor sediment reworking was a major factor during these years. In general, the qualitative distribution of the PAH below 8 cm is again consistent with combustion being the source, with inputs from the whaling station far exceeding allochthonous inputs.

The total *n*-alkanes are most abundant in the 6–14 cm and 30–36 cm regions. The lower peak is a legacy of the wasteful early years of whaling, as illustrated by the *n*-pentadecane and pristane data (both major constituents of whale oil). The upper alkane peak coincides with increasing post-1945 use of fuel oil, indicated by reduced carbon preference index (CPI) values[19] and enhanced phytane concentrations: CPI of 1.15 in 8–12 cm section compared with a normal value of 1.65 and phytane concentration of 0.3 μg per g in 10–14 cm section compared with a normal value of 0.1 μg per g.

However, the various indicators of the presence of petroleum are scattered but not coincidental throughout the sections dated 1945–69 (3.5–14 cm). Thus, if the phytane values[19] are examined, the greatest concentration of petroleum is from 1945 to 1955, if the ratio of parent to substituted tricyclics[20] is used, oil is present mainly in the 1959–69 regions whilst the amount and distribution of alkanes[19] suggest that 1955–60 are the years of major fuel oil input. No reasonable explanation is evident for this phenomenon, which must await a closer understanding of the fate of petroleum hydrocarbons in cold benthic ecosystems. Clearly these results represent evidence for the long-term stabilisation of petroleum components in these conditions, at least 20 yr—apparently the longest so far reported.

Ordovician conglomerates and the evolution of the Midland Valley

ORDOVICIAN and Silurian marine clastic sequences containing boulder bearing conglomerates overlie the Ballantrae ophiolite complex in South-west Ayrshire, Scotland. These conglomerates are thought to have been emplaced by submarine slides[1] or less viscous marine currents[2]. The Ordovician conglomerates accumulated at the toes of contemporary submarine faults downthrowing to the south[3] and in both their stratigraphy and palaeocurrents there is substantial evidence for a northerly source. The conglomerates contain clasts of the underlying ophiolite, metamorphic rocks, acid and intermediate volcanic and hypabyssal rocks and clasts of undeformed pink granite some of which are >80 cm in largest dimension. Dewey[4] and many subsequent workers[5] envisage these sediments as having accumulated on the southern margin of a continent under which oceanic plate was being consumed in a northerly dipping subduction zone. The time span of this subduction is subject to much speculation[6] but is generally thought to have ceased by Devonian time. We report here our investigations of the clasts in the southern Ayrshire conglomerates to elucidate (1) the nature and extent of plutonic activity in the area to the north of the subduction zone, and (2) the nature of the crust into which the plutons were emplaced.

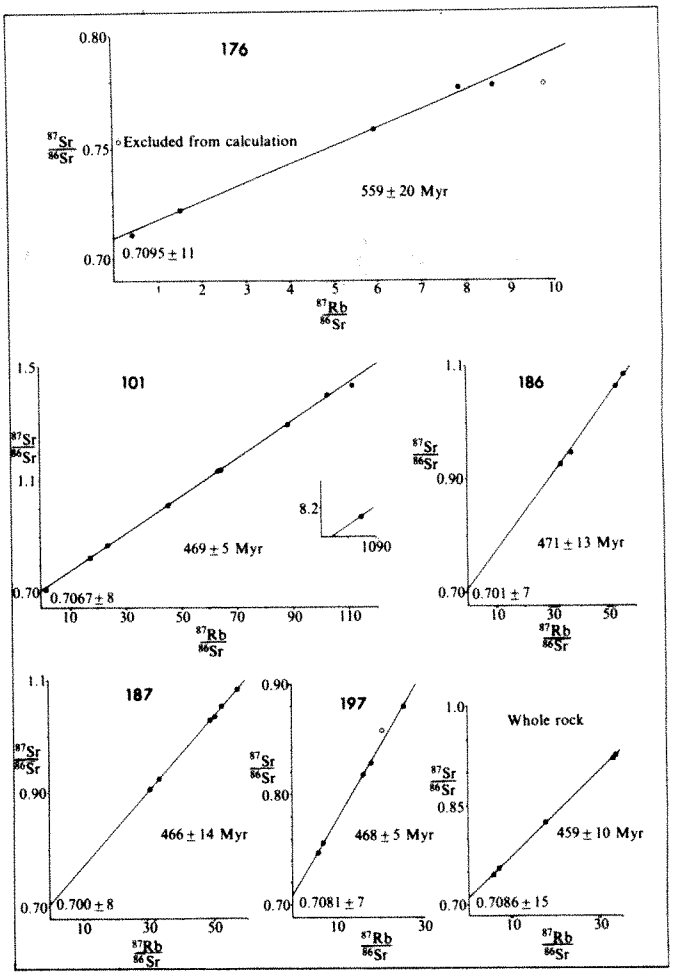

Fig. 1 Mineral isochrons of five different granite clasts and one composite whole rock isochron.

Rb–Sr isotope dilution analyses of these clasts follow the analytical methods described by Blaxland *et al.*[7]. Rb–Sr ages have been calculated, or recalculated, using $\lambda^{87}Rb = 1.42 \times 10^{-11}$ yr^{-1}. Analytical uncertainties at the 1σ level for $^{87}Rb/^{86}Sr$ and $^{87}Sr/^{86}Sr$ isotope ratios are ±0.7% and ±0.03% respectively. Seven analyses of the NBS 607 potassium feldspar standard yield average $^{87}Rb/^{86}Sr$ and $^{87}Sr/^{86}Sr$ values of 24.21 ± 11 (1σ) and 1.2006 ± 6 (1σ) respectively. The average $^{87}Sr/^{86}Sr$ value for NBS 987 standard $SrCO_3$ is 0.71020 ± 5 (1σ). Rb–Sr isochron ages were calculated using the least squares method of York[8]. All isochrons are concordant (MSWD < 2.5) or near concordant suggesting the observed scatter to be analytical rather than geological.

Rb–Sr analytical data are shown in Table 1. Mineral isochrons determined for five different granite clasts (minimum of 30 cm in longest dimension) and one composite whole rock isochron are plotted in Fig. 1.

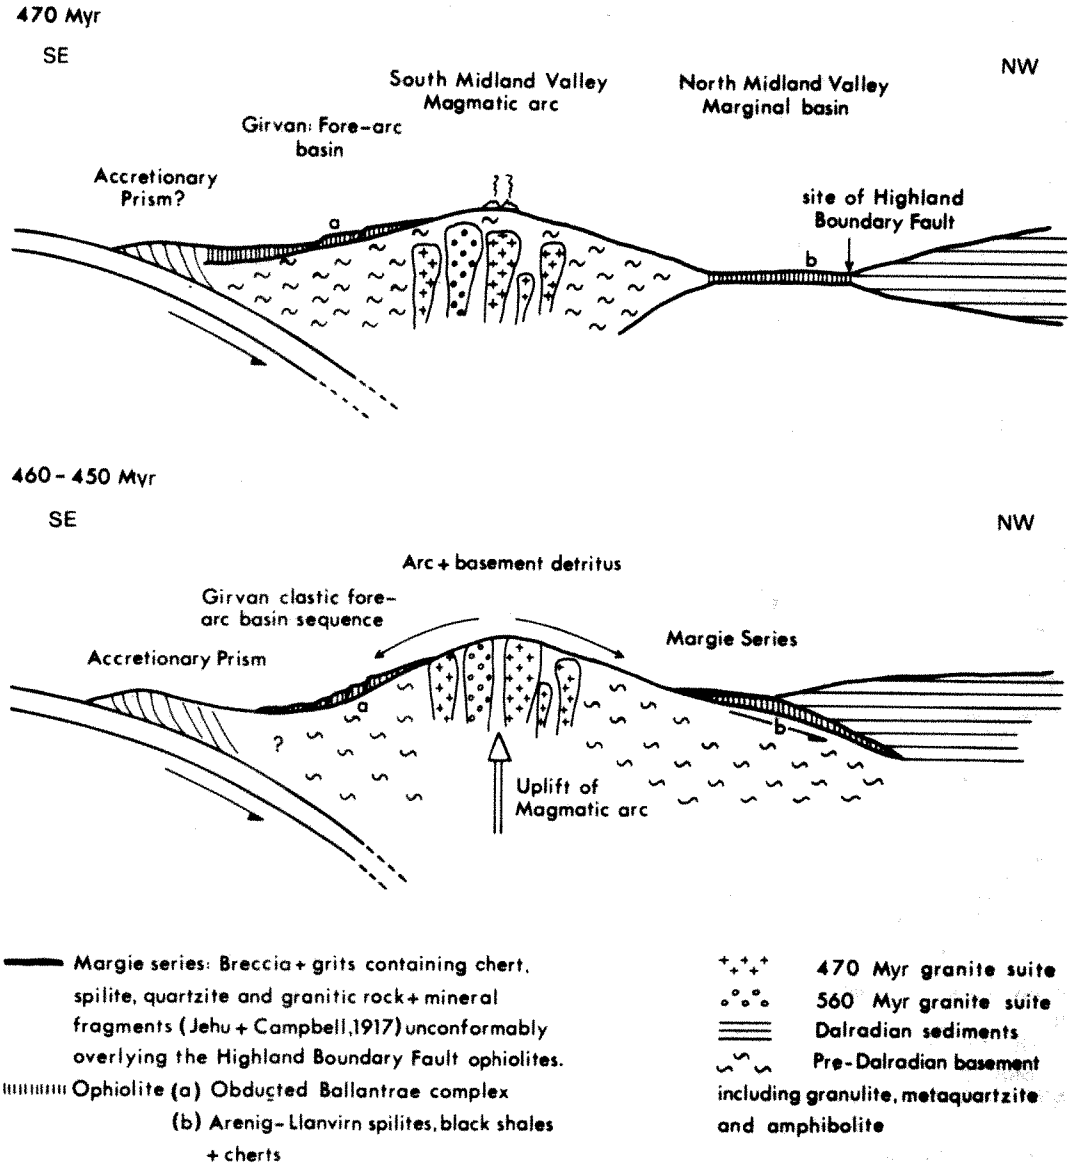

Fig. 2 Reconstruction of the Midland Valley during the Ordovician.

The age values obtained suggest a two-fold division defining one event at ~560 Myr and another at ~470 Myr. Sample 176, an undeformed non-perthitic biotite–chlorite bearing subsolvus granodiorite[9] yields an age of 559 ± 20 Myr. The other four clasts, 101, 196, 187 and 197 yield ages of 469 ± 5, 471 ± 13, 466 ± 14 and 468 ± 5 Myr respectively. These samples are less mafic, commonly microperthite-bearing subsolvus granites. The four whole rock points from the samples defining the ~470 Myr event were plotted along with another whole rock point from a chemically and petrographically similar clast (Fig. 1). These define a tentative isochron of 459 ± 10 Myr.

The initial $^{87}Sr/^{86}Sr$ ratios of three younger samples agree within experimental error (those for 186 and 187 were excluded as being ill defined and anomalously low) ranging from 0.7067 ± 8 to 0.7087 ± 15 and giving a mean of 0.7078 ± 10. The initial $^{87}Sr/^{86}Sr$ ratio for sample 176 is 0.7095 ± 11.

The age and stratigraphic position of the granite clasts places constraints on the Ordovician time scale. The dated clasts come from the Benan conglomerates of Llandeilo age. Petrographically similar clasts are, however, found in conglomerates ranging through to Llandovey in age[10]. Presently observed rates of uplift and erosion[11] suggest that surface exposure of the granites is possible in <10 Myr. This gives a maximum age for the base of the Llandeilo of about 460 Myr. This figure is in reasonable agreement with some published Ordovician time scales[12,13] based largely on K–Ar and Rb–Sr ages, but is irreconcilable with older ages based on fission track data[14].

Consideration of dispersal of the conglomerates and the size of the granite clasts indicate a provenance to the immediate north, in the south-west margin of the Midland Valley. The granite clasts have a similar petrography and age to the exposed pre and late tectonic granites in the Highlands. Ages of ~450 Myr are reported for many of the smaller granites of North-east Scotland[15] whereas the Carn Chuinneg–Inchbae granite is dated at 560 ± 10 Myr[16,17]. The known pre and late tectonic plutonic activity which preceded the ubiquitous ~400 Myr granites, relating to the final closure of the Iapetus Ocean, is therefore extended south of the Highlands.

The initial $^{87}Sr/^{86}Sr$ ratio of the Carn Chuinneg granite (0.710 ± 2)[16] is similar to that of sample 176—unless the 559 ± 20 Myr age for this rock is a cooling age and the high $^{87}Sr/^{86}Sr$ ratio reflects Sr isotopic equilibration on a mineral scale. In contrast, the initial $^{87}Sr/^{86}Sr$ ratios of around 0.708 for the ~470 Myr suite are significantly lower than the values of 0.714–0.717 for the ~450 Myr suite of Aberdeenshire granites[15]. Taken together, the 470–450 Myr Midland Valley–Aberdeenshire granites show a northerly increase in initial $^{87}Sr/^{86}Sr$ ratios. This pattern together with the high normative corundum and presence of muscovites in the northern granites[18] can be explained by increasing crustal involvement in the northern source. Although this evidence does not prove northward subduction the data are consistent with $^{87}Sr/^{86}Sr$ isotope ratio patterns of Mesozoic and Cenozoic subduction related granites in the western US[19,20] and such a model accords with

Table 1 Analytical data

many views on plate configuration in this region at that time[21].

The discovery of granite boulders of this age, together with consideration of the type and distribution of clasts in other Midland Valley conglomerates helps to refine existing models. Boulders and large cobbles of granite, quartz–porphyry, rhyolite and andesite present in Ordovician and Silurian conglomerates, suggest major intrusive and extrusive activity in the source area. The plutonic activity is now dated, and Kelling[22] in recording an influx of andesite fragments in Llandeilo greywackes has suggested volcanic fields in this region at the same general time as the intrusion of the younger granites of this study. This evidence is consistent with the development of an island arc in the southern margin of the Midland Valley reaching maturity in Lower Ordovician time. The existence of an island arc associated with the northward subduction has been previously postulated[4,23,24] but hitherto no evidence for its existence has been available.

Cobbles and boulders of metaquartzite, amphibolite and sheared granite occur in the northerly derived Ordovician conglomerates discussed here and the southerly derived Silurian conglomerates of the southern Midland Valley[25]. Metaquartzite thus formed part of the provenance in the Midland Valley at this time. However, as the 560 Myr granite is unfoliated it seems likely that the event which created the metamorphic assemblage pre-dated the early igneous episode. Furthermore, the presence of metaquartzite suggests ensialic deposition. Thus the evidence points to the existence of Precambrian basement under the Midland Valley, in accord with the original interpretation placed on granulite clasts of intermediate composition found in Carboniferous vents[26]. Mineral chemistry of these clasts indicate pressures and temperatures of metamorphism exceeding 11 kbar and 850 °C (ref. 27) and recent Sm–Nd isotopic work indicates a maximum Grenville age[28]. This evidence for late Precambrian continental basement under the Midland Valley agrees well with the LISPB north–south seismic profile across Scotland[29] and possibly supports both Kennedy[30] and George[31] who found evidence of a southerly source for the Upper Dalradian sediments.

The temporal and spatial setting of the probable post-Grenville quartzite deposition and its metamorphism in the late Precambrian, possibly very early Cambrian time, is critical to the evaluation of the early history of the Midland Valley block. It would, nevertheless, seem likely (also with evidence for Grenville basement under the Dalradian[32,33]) that the Midland Valley began its separate development after the rifting associated with the extrusion of the Tayvallich volcanics[34] which initiated the southward derived sediments of the Upper Dalradian.

The Tayvallich volcanism has been correlated with similar basic volcanism in Newfoundland (dated at 605 ± 10 Myr[35]) which has been attributed to the opening of Iapetus[36]. Our evidence, however, suggests that this rifting event was related to the formation of the first marginal basin along the southern margin of the North American Continent[23].

The serpentinite, spilite, radiolarian chert and black shale assemblages along the Highland Boundary Fault (HBF) are probably of Arenig–Llanvirn age[37]. The new data make it likely that these rocks were deposited behind the magmatic arc, in a marginal basin. The later closure of this basin, by subduction related under thrusting, then resulted in the preservation of a thin ophiolitic sliver along the HBF (see Fig. 2). This closure is likely to have occurred in Caradocian time, immediately after the deposition of the arenaceous 'molasse' of the Margie series, also preserved along the HBF. The closure resulted in the Highland Border rocks having a structural grain similar to those of the adjacent Dalradian, thus giving a spurious impression of structural unity in them both.

The evidence from the Tayvallich volcanics, the HBF suite and also the Ballantrae Complex[38] indicate that the southern margin of the North American continent comprised a series of marginal basins and associated microcontinents. It therefore seems improbable that the Grampian Orogeny resulted from a large-scale continent–continent collision. Consequently we conclude that the landmass which supplied the sediments of the Upper Dalradian was emplaced beneath the latter (see Fig. 2) resulting in the symmetrical folding and mushrooming of the Grampian orogeny and the dramatic uplift along the HBF[39].

Fly photoreceptor fluorescence is related to UV sensitivity

THE predominant photoreceptor type in flies, R1-6, contains a rhodopsin which absorbs maximally at around 480 nm. Light converts rhodopsin into a thermostable metarhodopsin peaking at around 580 nm (refs. 1–8). A curious discrepancy is the finding that the electrophysiological sensitivity is highest in the UV[5,9]—completely at variance with known rhodopsin absorption curves. Several possible explanations of the high UV-peak, including the presence of a UV-rhodopsin and waveguide effects, have recently been excluded[5–10]. Kirschfeld and co-workers have presented an alternative explanation[6,11], that R1-6 also contains a photostable pigment that absorbs UV light and converts the photopigment by energy transfer. This hypothesised sensitising pigment would most probably be a carotenoid, since vitamin A deprivation preferentially suppresses UV sensitivity[8,12,13]. Of course, vitamin A deprivation also lowers sensitivity by reducing the photopigment level[14,15]. Here we present further evidence for the existence of a vitamin A-dependent non-photopigment substance in fly photoreceptors. We measured fluorescence while simultaneously monitoring photopigment conversions and argue that the fluorescence is probably related to the UV-sensitivity.

This and previous studies on fly photoreceptors exploited the phenomenon of the deep pseudopupil. The deep pseudopupil is a superposition of the magnified virtual images of the distal photoreceptor endings located in several ommatidia (depending on the numerical aperture of the objective). It is observed by focusing at the centre of curvature of the eye[16–18]. Fluorescent deep pseudopupils from white-eyed fruit flies (mutants *cn bw Drosophila melanogaster*) under UV excitation are shown in Fig. 1. The six bright spots in Fig. 1*a* (high vitamin A reared fly) demonstrate that a fluorescing substance is located in the rhabdomeres, that is, the visual pigment containing organelles of the photoreceptors, of cells R1-6. This fluorescing substance is clearly vitamin A dependent, as the fluorescence is absent in flies deprived of vitamin A (Fig. 1*b*).

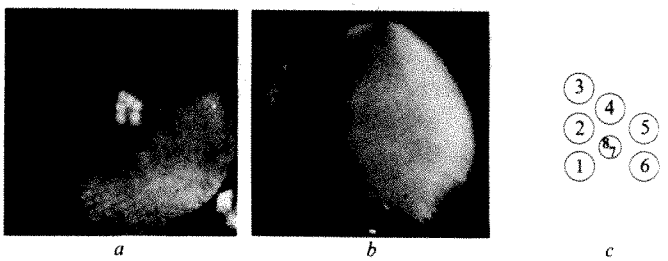

Fig. 1 UV-induced fluorescence photographed in the deep pseudopupil of the compound eye of completely intact and living white-eyed *Drosophila* (mutants *cinnabar* (*cn*) and *brown* (*bw*)), reared on diets high (*a*) and low (*b*) in vitamin A. In flies the rhabdomeres, which are the photopigment containing structures of the photoreceptors, are organised in a characteristic pattern (Fig. 1*c*). Only the rhabdomeres of cells R1-6 of high vitamin A flies (*a*) give an observable fluorescence to UV excitation in the deep pseudopupil. The vitamin A-dependent rhabdomere emission is pink (>550 nm). However, when superimposed on the blue autofluorescence of the eye, which is not vitamin A dependent, the fluorescent deep pseudopupil in vitamin A enriched flies has a whitish appearance. No distinct fluorescence is observed from the deep pseudopupil of vitamin A deprived flies (*b*).

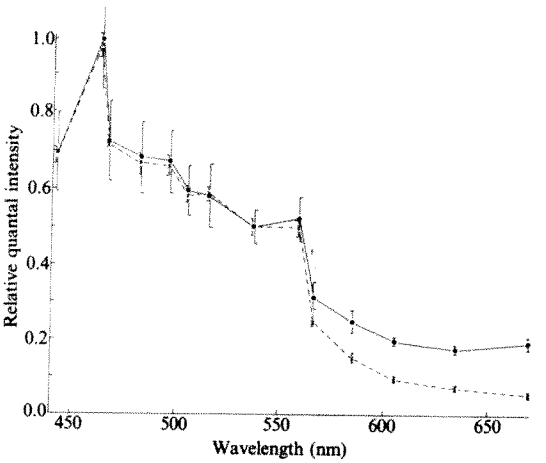

Fig. 2 Emission spectrum for UV excited fluorescence from the deep pseudopupil of *Drosophila*; exciting wavelength 365 nm. The relative quantal emission as a function of wavelength is plotted for high (●) and low (×) vitamin A reared *Drosophila* ($n = 4$ of each type, standard errors are calculated among different preparations).

The emission spectrum under UV excitation from the deep pseudopupil of flies fed on diets high and low in vitamin A was measured (Fig. 2). The difference, representing the emission spectrum of the vitamin A-dependent substance, is substantial only above 560 nm. Measurements were performed in a Leitz Dialux microscope equipped with incident fluorescence excitation and an EMI 9659 QB photomultiplier. An aperture delimited the area of all six photoreceptor images in the deep pseudopupil (≈80 μm diameter on the eye). For technical reasons we were unable to determine the emission spectrum above 670 nm. However, we suppose that the emission spectrum peaks in the red. In the experiments presented below (Figs 2 and 3), we measured fluorescence at >570 nm to accentuate the vitamin A-dependent proportion of the emission.

The magnitude of the emission is virtually identical whether the visual pigment molecules are either predominantly in the rhodopsin or in the metarhodopsin state (Fig. 3). Photopigment conversions were measured by antidromic transmission, that is, illuminating the head capsule, which is rather transparent in *Drosophila*, from the back, and then measuring the light leaving the distal part of the rhabdomeres[19]. Visual pigment conversion was monitored at 578 nm, near the peak of the metarhodopsin absorption spectrum ($\lambda_{max} \simeq 580$ nm for *Drosophila*)[4,5,8,13,20]. At the beginning of the experiment shown in Fig. 3 a high rhodopsin content was produced by a preceding 578 nm light. The transmission at 578 nm then is initially high, but it drops when the eye is irradiated by UV (365 nm) or blue (437 nm) light, due to conversion of rhodopsin into metarhodopsin. On the other hand, however, the fluorescence signal above 570 nm induced by the identical UV and blue irradiation intensities remains constant. This also proves to be the case in a comparable experiment performed on the white-eyed mutant *chalky* of the blowfly *Calliphora erythrocephala* (Fig. 3).

Since fluorescence was independent of whether the photopigment was in the rhodopsin or metarhodopsin state, it is likely that the vitamin A-dependent substance which fluoresces on UV excitation is related to the photoreceptor's UV sensitivity. To characterise this substance its excitation spectrum was found by

0028–0836/79/330581—03$01.00

© Macmillan Journals Ltd 1979

determining the light intensity needed to evoke a criterion emission >570 nm as a function of excitation wavelength. The spectral characteristics of the vitamin A-dependent substance were factored from background measuring from the deep pseudopupil of both high and low vitamin A reared *Drosophila*. A spectrum peaking in the UV with a tail in the blue was obtained (Fig. 4). (This tail could result from the long wavelength fluorescence which has been characterised for R7, another photoreceptor type, under blue excitation[21,22].) The nature of the fluorescing substance, of course, is still enigmatic, except for its vitamin A dependence. Nevertheless, in principle it qualifies well for the hypothesised sensitising pigment which functions in the visual process by transferring energy to both rhodopsin and metarhodopsin[5,6,8,11,21].

Note that a distinct red fluorescence under blue excitation was observed in R1-6 receptors of the housefly *Musca* by Franceschini[21,22], which was interpreted to be related to the amount of metarhodopsin. The data shown in Fig. 2 argue against this interpretation since fluorescence does not change during a monitored rhodopsin to metarhodopsin conversion. We have further shown that in *Drosophila* red fluorescence is only induced with blue excitation intensities 2–3 log units above those applied in the experiment of Fig. 3 (as well as for Fig. 4). Such extremely intense blue irradiation ($\simeq 10^{18}$ quanta $cm^{-2} s^{-1}$) also causes photolysis of the visual pigment. However, Franceschini has categorised different photoreceptor types by observations of this bright light induced fluorescence and we do not challenge his classification scheme[21,22].

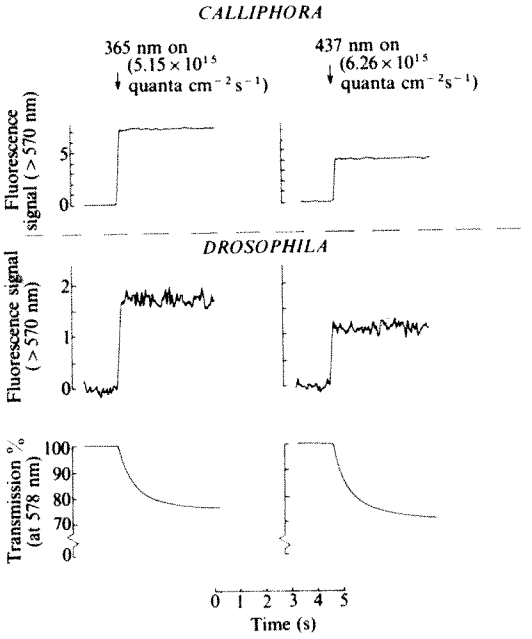

Fig. 3 Fluorescence and antidromic transmission measurements from the fly deep pseudopupil. Rhabdomere transmission was measured by illuminating the back of the rather transparent head of a *Drosophila* (that is antidromically) and determining the relative light intensity leaving the distal rhabdomere tips as visualised in the deep pseudopupil[19]. Yellow light of 578 nm wavelength was used to detect conversion of blue absorbing rhodopsin into yellow absorbing metarhodopsin induced by irradiating the eye with UV (365 nm) and blue (437 nm) light. (Initially a photoequilibrium with a high rhodopsin fraction was established by prolonged 578 nm light.) The indicated intensities were selected to induce conversion taking of the order of seconds. The fluorescence induced by these same intensities stays constant during this time period, and thus is independent from the state of the visual pigment molecules. The identical conclusion is obtained in the case of a white-eyed mutant (*chalky*) of the blowfly *Calliphora*. Vitamin A-enriched flies were used. From measurements on vitamin A deprived *Drosophila* it follows that background fluorescence due to eye tissue amounts to about 0.9 divisions in both cases of irradiation.

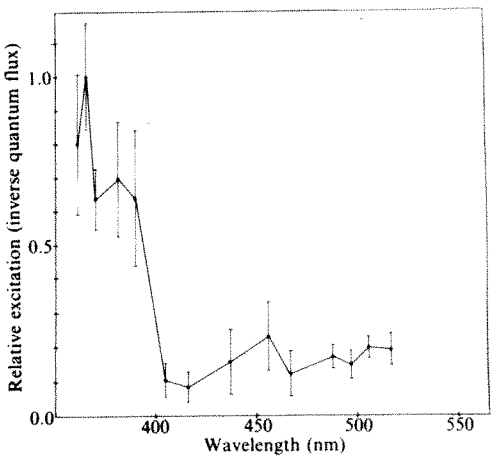

Fig. 4 Excitation spectrum of the vitamin A-dependent photostable substance of *Drosophila* photoreceptors. The intensities $I_h(\lambda)$ and $I_l(\lambda)$ needed to evoke a criterion signal c of emitted light >570 nm were measured in the case of high and low vitamin A reared flies respectively. (The identical aperture around the centre of the deep pseudopupil, enclosing all photoreceptor types, was applied throughout the experiments.) Let the spectral excitation of the vitamin A-dependent substance and that of the background be given by ε_s and ε_b respectively. Then it follows from $c = I_h(\varepsilon_s + \varepsilon_b)$ and $c = I_l\varepsilon_b$ that $\varepsilon_s \propto (I_h^{-1} - I_l^{-1})$. The assumed linearity of fluorescence signal with intensity was tested and verified. The data are from four high and four low vitamin A preparations with standard errors of difference shown.

It was claimed recently[23] that changes in the antidromic transmission caused by high intensities ($\simeq 5 \times 10^{15}$ quanta $cm^{-2} s^{-1}$) of blue light are too slow (minimum time constant >40 ms) to reflect visual pigment conversions. This is contrary to our interpretation of the Fig. 2 data. However, an extensive body of literature[2,3,5,18,24,25] is entirely consistent with the interpretation that these transmission changes are mediated exclusively by photopigment conversions. Moreover, we did not confirm the slow change in transmission[23] in our measurements of antidromic transmission from the deep pseudopupil of completely intact and living *Drosophila*. The time constant for the transmission change reflecting the speed of rhodopsin to metarhodopsin conversion was directly measured by applying light from a pulsed blue dye laser. The time constant is $\simeq 90$ μs, confirming predictions made on the basis of low temperature camera-flash experiments[26].

We thank Mr H. Leertouwer for collaboration, Dr N. Franceschini for exchanging information with us and Dr G. D. Bernard for comments on the manuscript. High vitamin A reared *chalky Calliphora* were from Dr J. Schwemer. This work was supported in part by NSF grant BNS-76-11921 (to W.S.S.).

Saccadic suppression by corollary discharge in the locust

DURING rapid eye movements, saccades, human subjects do not perceive movement of their visual surroundings, and their sensitivity to light flashes and moving objects is reduced. This phenomenon is known as saccadic suppression. The physiological basis of this suppression is not well understood. The necessity for a mechanism which allows discrimination between retinal image movement generated by the object and that generated by the subject was recognised by Helmholtz[1]. Sperry[2] proposed that along with the eye movement, the central nervous system generates a 'corollary discharge' into the visual centres that compensates for displacement of the retinal image, and von Holst and Mittelstaedt[3] independently postulated a similar 'efference copy' mechanism. Functionally significant efferent control has been demonstrated in several non-visual sensory pathways[4,5]. Such a mechanism could account for experimentally produced effects in human subjects[6,7]. The prevailing view[8–12], however, is that saccadic suppression in higher mammals is caused not by corollary discharge but instead by inhibition derived from the retinal image motion generated by eye movement. This view has been extended to include saccadic suppression of the visual movement detector system in crickets and locusts[13–15], in which the neural circuit performing the inhibitory function has been identified[15,16]. The experiments leading to this conclusion have all used passive movement of the animal with respect to the visual environment, or the reverse, and not true saccades. We have now investigated the effects of head movements by the locust on its visual responses, and report that movement detector neurones are strongly inhibited during the fast phase of optokinetic nystagmus and during voluntary saccades by a central nervous mechanism of the corollary discharge type. The effect of the inhibitory mechanisms of retinal origin are negligible by comparison.

In the locust movement detector system, one can study the neurophysiology of saccadic suppression in identified neurones that have well understood feature-detection properties. The lobula giant movement detector neurone and its tightly coupled postsynaptic cell, the descending contralateral movement detector (DCMD) neurone (the identified neurones of the locust movement detector system) are optimally responsive to novel, small-field stimuli in their hemispherical visual fields[14–18]. The DCMD neurones provide synaptic input to identified metathoracic motorneurones used for escape jumping[19,20] that can be provoked by novel changes in contrast. Locusts do not have moveable eyes and perform saccadic movements by turning their heads rapidly[21]. The changes in visual input thereby produced could inappropriately excite the DCMD neurones. This possibility is greatly reduced by the inhibition reported here that accompanies the fast phase of optokinetic nystagmus and voluntary saccades.

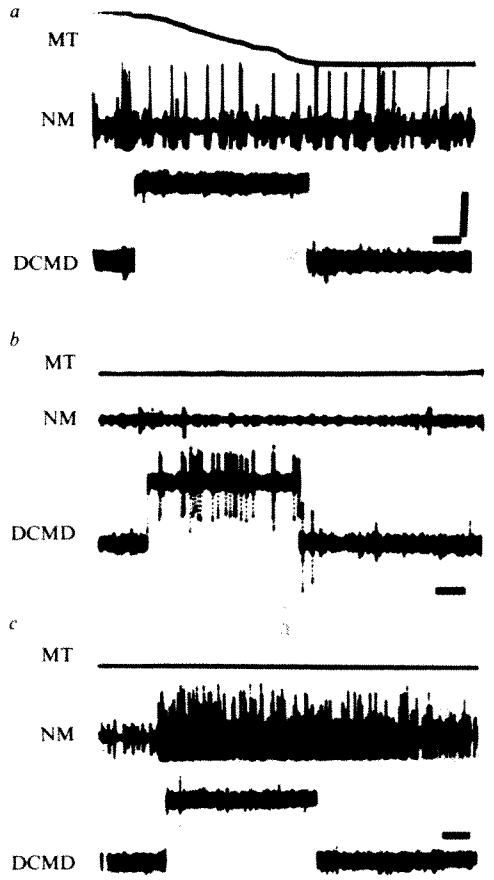

Fig. 1 Inhibition of the response of the DCMD to a moving spot stimulus during the fast phase of optokinetic nystagmus. *a*, A fast flick-back saccade of the locust's head is indicated by the abrupt decrease in the level of the signal produced by a capacitative movement transducer (MT)[34]. The onset of a burst of spikes of an M51 fast unit (NM) precedes the onset of the saccade by a brief interval. The high rate of firing of the M51 fast unit, triggers the stimulus, a moving spot of light produced by an oscilloscope beam, visible to the locust through a 15° window in the striped drum. The duration of the moving spot stimulus is indicated by the voltage step superimposed on the DCMD record (bottom trace). The DCMD neurone recording shows that there is no response to the moving spot stimulus during a fast flick-back. *b*, Thirty seconds after each saccade-triggered moving spot, a control stimulus, a second moving spot of light, similar to the experimental stimulus, excites the movement detector system in the absence of fast head turning, during the slow (following) phase of optokinetic nystagmus. The fast M51 unit (MN) is silent, and the DCMD responds vigorously to a moving spot stimulus. *c*, The locust's head is rigidly clamped to its prothorax, giving a constant value of the MT signal. The high frequency firing of M51 (NM) triggers a moving spot stimulus. The DCMD response is strongly suppressed during the M51 burst. Movement transducer calibration (vertical bar): 20°. Time scale (horizontal bar), 100 ms.

In the absence of movement of the visual field, locusts produce voluntary saccades, but they do so rarely. The fast phase of optokinetic nystagmus and voluntary saccades follow the same amplitude–duration relationship in locusts[21], and they are regarded as identical in higher mammals[22]. In order to make a large number of observations, therefore, saccadic movements were evoked in our experiments by tethering locusts inside a rotating striped drum, whereupon they readily perform optokinetic nystagmus, consisting of a slow (following) phase and a succeeding fast (flick-back) phase. Locusts were suspended by their pronotum, given a polystyrene ball to hold with their legs and left otherwise free to move. Single unit action potentials were recorded from muscle 51 (M51) of the neck, one of the muscles which turns the head[23], and from the ventral nerve cord axon of the DCMD by means of chronically implanted electrodes made from 100-μm insulated silver wire.

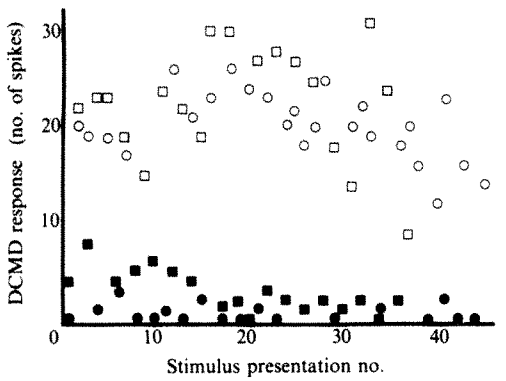

Fig. 2 The responses of the DCMD to two sequences of moving spot stimuli, recorded from (1) an open-loop condition locust (squares) and (2) from a closed-loop condition locust (circles). In both sequences experimental stimuli (solid symbols), triggered by fast-flick back motor commands, are followed 30 s later by control stimuli (open symbols), during which there is no flick-back command. Precautions were taken throughout all stimulus presentations to insure that a reduction of the DCMD response during saccades is a consequence of inhibition and not one of habituation of the response of the DCMD to repetitive stimuli[24]. A gating circuit effected a long minimal interval, 1 min, between successively triggered moving spot stimuli, and the control stimulus followed the experimental stimulus, rather than preceded it. The target stimulus was moved on the face of the oscilloscope by two independent, free-running waveform generators of slightly different frequency applied to the x and y deflection plates, so that it rarely traversed the same path twice.

The response of the DCMD to small moving stimuli is easily recognised as a burst of large single-unit action potentials delayed with respect to the stimulus by 50–75 ms (refs. 14, 17). During the fast phase of optokinetic nystagmus or during spontaneous saccades when the drum is stationary, the response of the DCMD is strongly inhibited; it responds not at all or with just a few acton potentials (Figs 1*a*, 2). During the slow phase of optokinetic nystagmus or if the locusts's head is stationary, the DCMD responds vigorously to optimal stimuli (Figs 1*b*, 2).

Activity of the fast and slow motor axons which excite M51 can be identified in extracellular recordings from the fibres of M51 as large (fast units) and small (slow units) spikes, respectively[23]. We find that inhibition of the DCMD is strongly correlated with high frequency burst activity of the fast motor units of M51 (Fig. 1*a*, c), and that the DCMD is not inhibited during low frequency tonic activity of either fast or slow M51 motor units (Fig. 1*b*). DCMD inhibition does not terminate sharply with the end of M51 fast motor unit bursts, but may continue afterwards for a duration of 200–300 ms. High frequency antidromic stimulation of the motorneurones to M51 does not produce inhibition of the DCMD. Inhibition of the DCMD is thus correlated with commands for fast turning of the head and not simply with activity of fast M51 motor units.

Relative movement of the eye and a complex visual background can suppress the response of the locust movement detector system[24,25] by mechanisms that are visual and not efferent in origin[15,16,18]. The inhibitory influence of the rotating striped drum in these experiments can be discounted. The contrast frequency, 0.02 Hz, produced by rotation of the striped drum alone is far too low to produce inhibitory effects of visual origin[15]. However, visual mechanisms for the inhibition of the locust movement detector system might well be activated and cause the inhibition we have described during the fast phase of optokinetic nystagmus when the locust's head turns with angular velocity as high as 300 deg s^{-1}. This possibility is excluded by two lines of evidence. First, the DCMD is strongly inhibited during spontaneous commands for voluntary saccades in a homogeneous white background. And second, after the head has been rigidly secured to the body (open-loop condition), the unilateral high frequency burst activity of the fast motor units of M51 which would normally cause rapid head movement still coincides with a period of strong inhibition of the DCMD response (Figs 1*c*, 2). This experiment also precludes proprioceptive feedback from head movement, via cervical and proprioceptive hairs[26,27] as a source of inhibition. (Elimination of proprioceptive feedback by securing the locusts head to its body or by elimination of neck hairs[21] reduces the frequency of occurrence of fast flick-backs but does not abolish them, contrary to Shepheard's[23] interpretation.

Further experiments, in which the nerves supplying the neck muscles are cut and motor unit activity recorded from the cut ends of the motor axons to M51, exclude proprioceptive feedback from neck muscle stretch receptors (should these exist) as a source of inhibition of the locust movement detector system during the fast phase of optokinetic nystagmus and voluntary saccades. The DCMD is as strongly inhibited in these conditions as it is when the neck muscles can contract. A command for rapid head turning is therefore a sufficient condition for inhibition of the locust movement detector neurones. Neither change in visual contrast, nor proprioceptive information produced by change in position of the head or muscle contraction, nor the visual signal produced by the rotating striped drum used to induce optokinetic nystagmus contribute significantly to this inhibition, which must therefore be efferent in origin and distinct from the previously described[15,16,18] visual inhibitory mechanisms of the locust movement detector system.

Relative movement of the eye and environment thus inhibits the locust movement detector neurones by either central or peripheral visual mechanisms. Presumably the same is true for the cricket movement detector system which is very similar to that of the locust[13,14]. These mechanisms do not effect inhibition of the entire locust visual system. For example, visual interneurones that are excited by relative movement of eye and background are not suppressed during optokinetic nystagmus[28]. The movement detector neurones, however, are inhibited predominantly by corollary discharge during saccadic movements, but visual reafference could function alone when movement is otherwise produced as in flight or locomotion. Central inhibitory mechanisms may be active here, as well.

Saccadic suppression in mammalian visual systems may involve mechanisms of both central and peripheral origin. However, there has been no neurophysiological demonstration of a functionally significant corollary discharge mechanism for saccadic suppression in any vertebrate, such as we have shown occurs in the locust. The similarities between the fast phase of optokinetic nystagmus in the locust and mammalian saccades[29,30], the former a continuous movement with a small amount of jitter, duration typically 200–300 ms and angular velocity maximally 300 deg s^{-1} (ref. 21), suggest that corollary discharges may at least participate in saccadic suppression of mammalian visual systems. A striking example of inhibition produced by corollary discharges associated with saccadic movements is found in the visual neurones of the superficial layer of the superior colliculus of the rhesus monkey[31,32,35]. Although they are in themselves poor sensory analysers, anatomical pathways exist[33] by which the suppression of the activity of the neurones of the superior colliculus could affect perceptual function through modification of the responses of the feature detector units of striate and extra-striate visual cortex. As in the locust, visual perception in higher mammals could thus be inhibited by corollary discharges that accompany saccadic movements as well as by retinal image motion[8–10,12].

We thank Drs D. Bentley and J. Palka for their helpful criticism of the manuscript and H. Amezquita and D. Helmgren for construction of apparatus.

Nuclear transplantation in teleost *Misgurnus fossilis* L.

ALTHOUGH the transplantation of somatic cell nuclei into eggs has been achieved in amphibian species[1,2], *Drosophila*[3] and some mammals[4,5], it is important to use further groups of animals because experience with amphibia has shown that the subsequent development of normal animals depends largely on the species used. We report here successful transplantation of nuclei from middle or late blastula into the eggs of teleost fishes. The eggs of teleosts have several distinctive features of structure, cleavage and early development which make nuclear transplantation more difficult than with amphibia. Teleost eggs are telolecithal, with the yolk segregated from the active cytoplasm. We used eggs and embryos of *Misgurnus fossilis* L. (loach). In this fish, 30–60 min after natural or artificial activation of an egg, part of the cytoplasm migrates to the animal pole, forming a small polar cap where the nucleus is situated, completing meiotic division[6]. Thus, nuclei must be introduced into the animal pole region which occupies not more than one-tenth of the total egg.

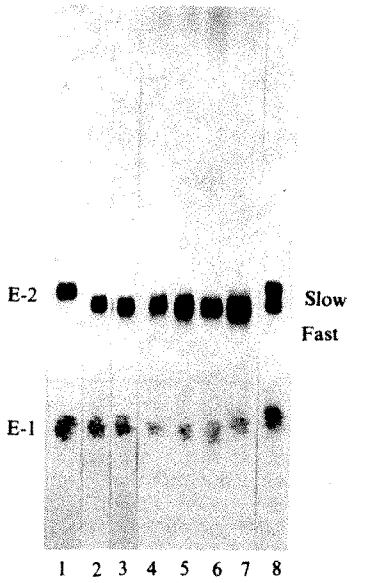

Fig. 1 Esterases of larvae obtained from eggs supplemented with blastulae nuclei. Individual larvae 120 h old were homogenised in a 1% solution of Triton X-100 in distilled water. Each homogenate was centrifuged (2,000*g* per 10 min) and aliquots of supernatant were subjected to polyacrylamide gel disc electrophoresis in 1-mm diameter tube. Esterase bands were identified using a slightly modified method of Sims[10]. The substrate was α-naphthylacetate. The start is at the top and the anode is at the bottom. Two zones of esterase activity are revealed, the more cathodal being E-2 carboxylesterase. Gels 1 and 2 show the mobility of two allelic variants of E-2 slow and fast isoenzymes in homozygous larvae, respectively. Gel 8 results from a control mixture made from the homogenate analysed in gel 3 and from a standard slow E-2 preparation.

The procedure was basically similar to that of Briggs and King[1]. Eggs of *M. fossilis L.* were obtained by injection of females with chorionic gonadotropic hormone (100 mequiv. per 100 g body weight). They were activated by placing them in Petri dishes with tap water; activated eggs became attached by their vegetal poles to the bottom of the dish. After 30 min, when the polar cap had formed, the water was replaced by Niu–Twitty solution, which served as a medium for further experiments. A blastodisk of mid-blastula stage was removed from the yolk and placed in Niu–Twitty solution without Ca^{2+} and Mg^{2+}. Dissociation was complete after 5–10 min. A single cell ($\sim$50 μm in diameter) was sucked into a micropipette of inner diameter about 35 μm. The end of the pipette was inserted into the egg at

Table 1 Nuclear transplantations in *Misgurnus fossilis* L.

Table 2 Ploidy estimation in blastulae and gastrulae obtained

Nuclear transfers from mid-blastulae	Stage	Embryos analysed: Number	No. of embryos: Anucleate subhaploid	Haploid	Diploid	Triploid	Tetraploid
To enucleated eggs	Blastula	30	11	0	16	0	2
	Gastrula	9	0	0	9	0	0
To non-enucleated eggs	Blastula	19	3	2	11	1	2
	Gastrula	6	0	0	5*	1	0
Control	Blastula	7	0	0	7	0	0

Blastodisks isolated from the yolk were fixed in a mixture of alcohol and acetic acid in the ratio 1:3 for 24 h, washed with 70% at 5 °C and stained with acetorcein. Stained blastodisks were squashed in a drop of 45% acetic acid. In each blastodisk preparation 8 to 10 metaphase plates were chosen to calculate chromosome number. The diploid set in *M. fossilis L.* consists of 100 chromosomes[8]. The number of chromosomes in preparations of metaphase plates was counted to an accuracy of ± 10%, as shown by the analysis of untreated diploid embryos. We therefore took as diploids all treated embryos in which we counted 100 ± 10 chromosomes. Triploid and tetraploid embryos were those with 150 ± 15 or 200 ± 20 chromosomes, respectively. Embryos were termed anucleate or subhaploid if most of the cells had no nuclei and if the few cells which contained nuclei were subhaploids. In one of two blastulae presented above as haploids we counted 50 chromosomes in each metaphase plate analysed and in another 50 ± 5 chromosomes. * Some metaphase plates in these embryos contained a subhaploid (< 20) or polyploid (> 200) number of chromosomes.

equatorial level and the contents were injected into the polar cap region. The operation was carried out within 60 min of activation. Operated eggs were incubated in the same medium at 16–18 °C for 10 days, sufficient for the formation of actively feeding larva.

Two series of experiments were carried out, with and without enucleation of eggs. Enucleation was achieved by X-ray irradiation in an appropriate dose to inactivate the nuclei of loach eggs[7]. As our results show (Table 1) irradiation produced almost complete inactivation of the female pronucleus, while the cytoplasm remained able to support normal development at least to the larval stage. We used 791 enucleated and 320 non-enucleated eggs, and into each of them we transplanted a single somatic cell nucleus (together with cytoplasm) from the mid-blastula. Of the 200 gastrulae thus obtained, 41 developed to the prelarval stage or into actively feeding larvae. The development of most embryos stopped at some point before these stages and in many cases there were evident abnormalities. Some embryos were lost after the feeding larva stage, but others were quite normal and were either used for analysis of enzymes or fixed as total preparations. Unfortunately, we have not been able to maintain the development of loach larvae beyond the stage of actively feeding larva in laboratory conditions.

To investigate whether this embryonic development was determined by the transplanted nuclei, we looked at the karyotypes and carboxylesterase (EC 3.1.1.1.) isoenzymes of the embryos. Table 2 shows that most of the blastulae were diploid, although some were tetraploid. This was possible only if the transplanted nuclei had participated in the development of the embryos. During transplantation some cytoplasm, including the centriole, is transferred from the somatic cell into the egg together with the nucleus. Thus, it might be said that the centriole provokes 'parthenogenetic' cleavage; however, if this were so, only blastulae with an abnormal chromosome set should be formed. Indeed, when enucleated eggs are fertilised with irradiated sperm and are supplemented with sperm centrioles, they begin to cleave but yield only embryos with abnormal chromosome sets, developing no further than the blastula stage.

Transplantation into non-enucleated eggs yielded about the same proportion (~50%) of cleaving embryos which formed blastulae, and about 10% developed into normal larvae. This could not have happened without the transplanted nuclei because unfertilised and artificially activated eggs of *M. fossilis L.* never cleave. Again, it might be said that cleavage was provoked by the introduction of the somatic cell's centriole, but if so, the embryos would have been haploid, for when fertilised with irradiated sperm, loach eggs cleave but spontaneous diploidisation of a female pronucleus does not usually occur and only haploids are formed[7]. Table 2 shows the tentative estimation of the ploidy of blastula cells. We expected that they would be either mainly haploid (if parthenogenetic development was induced by the introduced centriole) or triploid due to fusion of the transplanted nucleus with the female pronucleus. Most embryos seemed to be diploids, with only a small part of the blastulae having cells with 1*n* chromosomes (or even fewer).

Two alleles for carboxylesterase are known in *M. fossilis L.*[9], coding for two distinct forms of the enzyme (E-2), electrophoretically fast and slow (Fig. 1, gels 1 and 2). Maternal E-2 synthesised at oogenesis has been shown to disappear within 120 h, after which only the esterase controlled by the larval genome is found[9]. When nuclei of blastulae homozygous for fast E-2 were transplanted into enucleated eggs from females homozygous for slow E-2, only fast E-2 was found in the larvae that developed (Fig. 1, gel 3). When nuclei from blastulae homozygous for fast E-2 were transplanted into non-enucleated eggs from blastulae homozygous for slow E-2, five larvae out of six obtained had only fast E-2 (Fig. 1, gels 4–6); in one larva there was a trace of slow E-2 in addition to fast E-2 (Fig. 1, gel 7), indicating partial function of E-2 genes characteristic of the female pronucleus. Probably, either the whole pronucleus or the chromosome carrying the relevant gene was preserved in this larva. Only the blastulae and gastrulae were karyotyped and most of them seemed to be diploid, although there were polyploid individuals among them. Based on these data we consider that our larvae were mainly diploids, and that in the experiments with non-enucleated eggs the female pronucleus was eliminated in the embryos, although it may have been preserved in some cases, yielding triploids, as reported for amphibia[11]. The possibility that we measured some maternal enzyme activity can be discounted because maternal E-2 esterase synthesised at oogenesis disappears within 120 h (ref. 9) and our analyses were made on larvae older than 120 h. Therefore, we applied an enzyme analysis to indicate that there was little or no activity of the genes of recipient eggs in the resultant larvae.

This cannot be attributed to the fact that cytoplasm of the blastula cell which contained some amounts of donor-like enzyme was introduced to the recipient egg because this cytoplasm constituted less than 0.1% of the egg cap cytoplasm[12] and the exogenous enzyme was further diluted during cell multiplication.

Expression of genetic resistance to an oncogenic herpesvirus at the target cell level

THE oncogenic potential of herpesviruses has been demonstrated in several species and herpesviruses have been strongly implicated as aetiological agents of various human neoplastic diseases[1,2]. The extreme heterogeneity of human populations makes genetic analysis of mechanisms of host resistance to neoplastic disease in man a difficult task. Another herpesvirus, Marek's disease virus (MDV), is the aetiological agent of a naturally occurring lymphoma of chickens, Marek's disease (MD) (for review see ref. 3). MD is the animal model for Burkitt's lymphoma of man in which the Epstein–Barr virus (EBV) has been strongly implicated[4]. At least two loci are associated with resistance to MD: the major histocompatibility complex (MHC)[5,6] and a non-MHC locus[7]. The mechanism of MHC-associated resistance may involve an active rejection of MD tumour cells[5]. We now report data which strongly suggest that non-MHC-associated genetic resistance is expressed at the level of the target cell for malignant transformation.

The target cell for neoplastic transformation by MDV is generally thought to be a T lymphocyte[8]. The tentative association of the *Ly-4* locus, which codes for alloantigenic markers present on T cells, with the degree of susceptibility to MD[7] led us

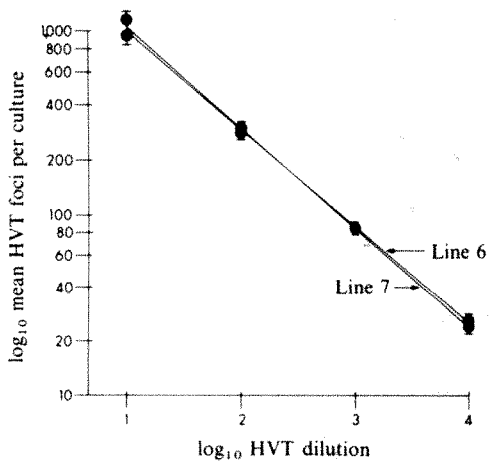

Fig. 1 Secondary chick embryo fibroblasts (CEF) were prepared from 10-day line-6 and line-7 embryos and propagated in Linbro multi-well trays. Lyophilised FC126 strain HVT vaccine was reconstituted with medium and centrifuged at 500g for 15 min to remove large cell debris. Four replicate wells were infected with each serial 10-fold dilution of this preparation, the highest concentration of which had yielded 1.25×10^4 focus-forming units per well when assayed previously on Hy-line SC CEF. HVT foci were stained with Giemsa stain and counted at 64 h post-infection. Error bars indicate 1 s.d. from the mean.

Table 1 Infectious centres induced by spleen cells exposed to HVT *in vitro* or MDV *in vivo*

Spleen cell source	HVT lesions per 1×10^7 cultured spleen cells	MDV lesions per 5×10^5 injected spleen cells
Line 6	33.5 ± 25.5	9.4 ± 6.5
Line 7	223.9 ± 38.0	38.6 ± 3.6

For determination of infectious centres after *in vitro* exposure to HVT, aliquots of the spleen cells used for the HVT adsorption studies of Fig. 2 were washed three times in medium and cultured in RPMI-1640 with 10% fetal calf serum for 24 h at 37 °C at a density of 5×10^6 spleen cells per ml. Cells were then washed twice in medium and infectious centres were assayed *in ovo* according to the method described previously[9]. For determination of infectious centres after *in vivo* exposure to MDV, groups of five Hy-line SC (B^2/B^2) third-party chicks were given 500R of γ-rays on days 3 and 7 post-hatching and reconstituted with 1×10^8 spleen cells obtained from 6-week-old line-6 or line-7 donors. Following a 7-d period of natural exposure of the recipients to MDV, spleens from each group were pooled and the number of infectious centres was assayed *in ovo*[9] in B^2/B^2 eggs histocompatible with the donor MHC. Background host-specific infectious centres in unreconstituted, γ-irradiated, MDV-exposed chicks formed less than 15% of the observed totals and this value was subtracted from the data to obtain donor-specific infectious centres. Error values are 1 s.d. from the mean.

to postulate that non-MHC-associated resistance could be due to differential infectivity, transformability or proliferation of the target cell for MDV. Susceptible line-7 birds display a much higher leukocyte-associated titre of MDV than resistant line-6 birds following natural exposure to MDV[7]. Although this observation is consistent with the target-cell hypothesis, it is explained equally well by immune surveillance mechanisms. However, differential infectivity is also demonstrable in line-6 and line-7 embryos[9] at stages of development during which immune mechanisms are unlikely to be involved. This finding supports the target cell hypothesis rather than classical immunological surveillance mechanisms. Chickens which are genetically resistant to MD nevertheless become infected with and shed virulent MDV. Furthermore our own evidence shows that embryonic fibroblasts from lines 6 and 7 are equally permissive to *in vitro* infection with a related herpesvirus, the herpesvirus of turkeys (HVT, Fig. 1). Similar observations have been made for MDV infection of adult kidney cells. However, one cannot assume from this that genetic resistance to lymphoma development could not be due to differential infectivity at the level of the target cell. Productive infection of fibroblasts or epithelial cells by MDV, a process which may reflect a capacity for infection at the level of the whole animal, is not equivalent to infection and neoplastic transformation of T lymphocytes and, thus, may not be subject to the same genetic restrictions. To determine whether line-6 and line-7 lymphocytes display differences in viral adsorption or infectivity demonstrable *in vitro*, spleen cells from these lines were incubated with HVT, pelleted by centrifugation, and the amount of infectious virus remaining in the supernatant was assayed on chick embryo fibroblast monolayers. HVT was used in these studies because it is much more stable in cell-free form than MDV, but it may be assumed that these two very similar herpesviruses use the same cellular receptors.

Spleen cells from line-7 (susceptible) birds adsorbed HVT in a dose-dependent fashion but line-6 spleen cells adsorbed less virus at the concentrations tested (Fig. 2). This difference is highly reproducible: this experiment has been repeated six times with the same result. In parallel experiments not presented here, line-7 thymocytes also adsorbed significantly more HVT than did line-6 thymocytes[10]. However, the difference in adsorptive capacity of spleen cells was greater than that observed for thymocytes, as might be expected if a mature T lymphocyte were the target for MDV.

Table 2 Marek's disease mortality in chickens which received thymus transplants

	Group				
	A Line 7 N→Line 6 TX	*B* Line 7 γR→Line 6 TX	*C* Line 6 N→Line 6 TX	*D* Line 6 TX	*E* Line 6 Sham TX
Total	38/72	10/24	6/36	12/46	3/17
%	52.8	41.7	16.7	26.0	17.6

Newly hatched chicks were thymectomised or sham-operated as described previously[19]. For thymus transplants, thymus lobes were cut into two or three pieces and immediately transplanted subcutaneously lateral to the oesophagus in areas which had been vacated by the host's thymus lobes. At least one entire thymus equivalent (14 lobes) was transplanted per recipient. On day 2 post-hatching chicks were contact exposed to MDV by housing them next to 4–6-week-old chickens which had been inoculated with 10,000 *in ovo* lesion-forming units[9] of the BC-1 isolate of MDV[20]. The incidence of MD-specific deaths was recorded for 14 weeks at the end of which significant losses due to MD had ceased. N = normal, non-irradiated donor thymus; TX = thymectomised; γR = 1,000R γ-ray irradiated donor thymus. Using Fischer's calculation of exact probability, $P = 0.00046$ for a two-tailed comparison of groups *A* and *C* and $P = 0.0033$ for a one-tailed comparison of groups *B* and *C*.

Following viral adsorption, the number of infected cells of each type was estimated after the cells had been washed and incubated for 24 h. Line-7 spleen cells induced 6.7 times more infectious centres than did the line-6 spleen cells (Table 1). To confirm this observation for MDV *in vivo*, line-6 and line-7 spleen cells were adoptively transferred into separate groups of irradiated, histocompatible, third-party recipients which were then naturally exposed to MDV. Following this procedure, over four times more line-7 spleen cells than line-6 spleen cells were infected with MDV (Table 1).

These experiments suggest that it might be possible to make a resistant (line-6) bird more susceptible to MD by providing a source of susceptible (line-7) target cells. For this purpose, two sources of line-7 cells were used for transplantation into line-6 recipients. First, we prepared classical haematopoietic chimaeras following the intravenous injection of line-7 embryonic spleen cells into line-6 embryos and found that this procedure did not result in a significant increase in MD mortality[10]. Thus, the mere presence of line-7 haematopoietic cells apparently did not result in an increased mortality due to MD. To provide a more direct source of T lymphocytes, the putative target cells for transformation, we transplanted line-7 thymuses into newly hatched, thymectomised line-6 recipients. The pooled data from six experiments (Table 2) show that this procedure rendered the line-6 birds much more susceptible to MD. We observed no significant differences in MD mortality between thymectomised line-6 birds, sham-thymectomised line-6 birds and thymectomised line-6 birds which received a line-6 thymus transplant. This finding serves to control for the possibility that the line-7→line-6 transplanted birds showed a higher mortality simply because the donor thymus failed to reconstitute a depleted T-cell compartment. In addition, there have been no reports that thymectomy *per se* has an effect on MD mortality, although neonatal thymectomy combined with irradiation[11] or anti-T cell serum treatment[12] can affect MD mortality and virus titre.

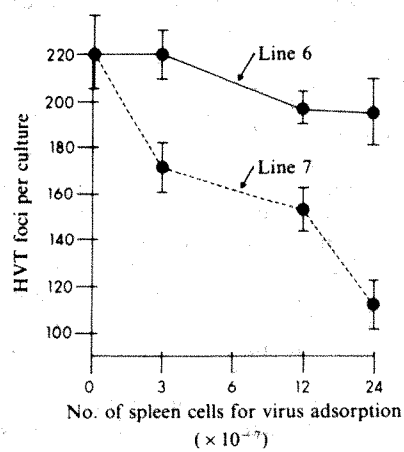

Fig. 2 HVT was prepared as described in Fig. 1. Cell suspensions from spleens of 3–4-week-old donors were prepared by collagenase digestion, washed three times in medium and mixed with aliquots of HVT. Only those cells having morphologies characteristic of lymphocytes were counted and included in the calculation of spleen cell number for data shown in Fig. 2 and Table 1. Virus adsorption was carried out at room temperature for 1 h and the cells were then pelleted by centrifugation. The amount of infectious HVT remaining in the supernatant was estimated by focus formation on replicate cultures of CEF of Hy-line SC origin. Error bars indicate 1 s.d. from the mean.

The finding that transplantation of susceptible thymuses made the resistant birds more susceptible but that the presence of haematopoietic cells from the susceptible line did not, could mean that (1) thymus transplants simply provide more susceptible target cells at the appropriate stage of differentiation than a more primitive population of embryonic spleen cells, or (2) the genotype of the thymic micro-environment may influence the target-cell phenotype, as stem cells can be induced to undergo differentiation into mature T cells in the thymus gland. In support of the latter possibility, we have found that transplanted, irradiated (1,000R) line-7 thymuses increased the susceptibility of line-6 chicks (Table 2). Further experiments will be necessary to determine whether line-6 stem cells undergo a phenotypic change under the influence of line-7 thymus glands. One prediction would be that unlike the adoptive transfer of embryonic spleen cells, adoptive transfer of line-7 adult spleen cells, a portion of which have presumably migrated through a susceptible thymic microenvironment, should be sufficient to increase susceptibility to MD. These experiments are in progress.

Thus, we have presented data which strongly suggest that genetic resistance to an oncogenic herpesvirus can be manifested at the level of the target cell. Genetic resistance to C-type RNA viruses at the cell level has been shown in several systems[13–16] but we believe that our studies represent the first demonstration of cellular resistance to an animal DNA virus. We transplanted susceptible thymuses into resistant animals and made them much more susceptible to oncogenesis. Conversely, Shieh and Sevoian[12] reported no significant effect of transplantation of a susceptible thymus into a thymectomised resistant host in lines of chickens in which resistance was associated with the MHC. Our data provide strong evidence that the target cell for MDV-induced transformation is a T lymphocyte. The mechanism of resistance at the target T-lymphocyte level remains unknown but our viral adsorption studies suggest that resistant birds may have target cells with fewer virus receptors, receptors of lower affinity for virus, or fewer target cells with identical receptors. That differences may exist between line 6 and line 7 in the size of T-cell subpopulations is suggested by other studies which show that line-7 birds possess three times as many allo-reactive T cells as line-6 birds[17] and that susceptible T cells may proliferate at a greater rate than resistant T cells[18]. In view of this, this, the observed differences in MDV infectious centres assayed *in ovo* are indicative of target cell phenotype, but may reflect the capacity of inoculated cells to divide and/or

spread in the embryo. A role for such post-adsorptive mechanisms can only be ruled out by the careful use of serological and physical cell markers.

Feedback inhibition by human primed T-helper cells

STUDIES in animal models, in particular that of the murine system, have revealed that the sequence of events leading to an antibody response is similar to other complex biological processes in that they are controlled by interrelated regulatory mechanisms[1,2]. In man helper activity which regulates the antigen-induced antibody response *in vitro* is initiated by T lymphocytes bearing receptors for the Fc fragment of IgM ($T\mu^+$ cells), whereas suppressive activity can be induced in T cells capable of binding the Fc fragment of IgG ($T\gamma^+$ cells)[3]. We present here data which indicate that $T\mu^+$ cells, apart from providing help in the human antigen-driven process of B-cell activation, are also capable, in certain conditions, of inducing a subpopulation of unprimed T cells to suppress an antigen-induced antibody response.

As has been reported[4], the *in vitro* induction of suppressor activity by $T\gamma^+$ cells requires the presence of a relatively high dose of antigen in the culture, whereas helper activity of $T\mu^+$ cells prevails over suppressor activity if a relatively low dose of antigen is applied to a culture of unselected human peripheral T and B cells[5]. In an attempt to induce and measure helper activity without simultaneous activation of $T\gamma^+$ cells, $T\mu^+$ cells were isolated from the unselected T cells, added to purified B cells and stimulated by a dose of antigen known to induce a suppressor activity in cultures containing unselected T cells.

As can be seen in Table 1 (and ref. 3), considerable numbers of plaque-forming cells (PFC) were obtained, indicating that effective T-helper activity is generated if a high dose of antigen is used. Moreover, when isolated $T\mu^+$ cells were primed by preculturing the cells with a high dose of sheep erythrocytes (SE) for 6 days and subsequently added to purified B cells, a PFC response is obtained that exceeds the number of PFC of B-cell cultures to which only unprimed $T\mu^+$ cells were added (see Table 1). When, however, primed $T\mu^+$ lymphocytes were added to a suspension of B cells supplemented with unselected, unprimed T cells, a low PFC response was observed, indicating that a negative regulatory activity had been generated by the subsequent addition of unselected, unprimed T cells. Figure 1 also shows that as the number of primed T-helper cells, added to a culture of unselected, unprimed T cells and B cells, increases, suppression also increases; this meets the definition of a feedback type of suppression.

Shore *et al.*[6], who induced optimal helper activity by using 24-h primed $T\mu^+$ cells, did not observe any sign of a feedback inhibition of the antibody response when the cells were cultured with unprimed T cells and B cells. On the contrary, these cells reacted as adequate primed T-helper cells.

Our results lead us to suggest that during the 6×24 h priming period some differentiation and/or education of $T\mu^+$ cells occurred which resulted in their capacity to suppress the B-cell response. However, our data do not allow us to state definitely that a feedback signal is provided by $T\mu^+$ helper cells as such. Within the $T\mu^+$ subset, cells could be present which do not express antigen-specific help, but which are programmed exclusively to induce a feedback type of suppression. Cantor *et al.*[7], however, when describing a similar system for the mouse, reported that the primed cell which is capable of delivering the feedback signal in the murine system, is a cell residing in the Lyt 1^+, Qa 1^+ subpopulation. It appears that the Lyt 1^+, Qa 1^+ cell is a T-helper cell capable of synergising with a Lyt 1^+, Qa 1^- T cell to generate optimal helper activity. We cannot yet substantiate our hypothesis further because we are unable to visualise membrane structures that will allow the recognition of possible subsets of $T\mu^+$ cells.

Table 1 Regulation by SE-primed T helper cells

Primed T cells	Assay system*	PFC per 10^6 Lyt
None	$+3.5\ T\mu^+$	2,333 (1,514–2,922)
$3.5\ T\mu^+$	None	3,804 (2,581–4,201)
$1.0\ T\mu^+$	$+2.5\ T^\dagger$	178 (0–364)
None	$+2.5\ T^\dagger + 1.0\ T\mu^+$	1,875 (900–2,224)

* Assay system: 1.5 B cells plus 5.0 SE (cell numbers $\times 10^6$) plus indicated T-cell fractions.
† Unselected, unprimed T cells.

For the induction of PFC to SE, cultures were set up in 17 × 100 mm tissue culture tubes (Falcon) containing 1.5×10^6 B cells in 10 ml of culture medium consisting of RPMI-1640, 25 μg Fungizone, 100 μg penicillin, 100 IU streptomycin, 2-mercaptoethanol (0,02 M), L-glutamine (2 mM) and supplemented with 10% serum derived from AB^+ donors (AB serum) which had been preabsorbed with SE to prevent artefactual plaque formation[11]. To these cultures various T-cell fractions were added: unprimed, unselected T cells ($T^\dagger$) and/or $T\mu^+$ lymphocytes, together with 5×10^6 SE as antigen. Cultures were kept in a humidified atmosphere of 5% CO_2 in air. After culturing the cells for 6 d, cells were collected, washed twice in RPMI-1640 at 4 °C and assayed for PFC according to Dosch and Gelfand[12]. The data shown are expressed as the arithmetical mean of values obtained in five individual experiments. Within each experiment determinations were done in sixfold. Values in parentheses represent the ranges. *Priming procedures*: $15 \times 10^6\ T\mu^+$ cells, which were isolated as described in Table 2 legend, were cultured with 15×10^7 SE in the inner tube of a Marbrook–Diener type of culture tube. The inner tube contained 3 ml of culture medium supplemented with 15% SE-absorbed AB serum. The outer tube contained the same medium as the inner tube with the exception that the medium was supplemented with 5% fetal calf serum instead of 15% AB serum. The Marbrook–Diener cultures were kept for 6 d in a humidified atmosphere of 5% CO_2 in air. After the culture period the primed cells were freed of the SE by NH_4Cl-induced lysis. The cells were then washed twice with RPMI-1640 containing 5% AB serum. Viability of the cells was tested for by Trypan Blue dye exclusion which always exceeded 90%.

PBL, isolated according to Bøyum[13], were separated into T and non-T cells by two cycles of EAC-rosetting and subsequent density gradient centrifugation on Ficoll–Isopaque ($\rho = 1.077$)[3]. The non-T fraction was depleted of non-lymphoid cells by adherence to plastic and recovered by gently scraping with a rubber policeman as described in ref.3. *$T\mu^+$ cell isolation*: The T cell fraction was incubated with 3 mM theophylline (Sigma) for 60 min at 37 °C (ref. 14). Cells were then collected by centrifugation at 4 °C and immediately mixed with a 50-fold number of SE[15]. This mixture was layered on Ficoll–Isopaque ($\rho = 1.077$) and centrifuged for 30 min at 1,000 g. After the separation procedure the theophylline-resistant cells in the pellet were freed of contaminating SE by lysis with NH_4Cl and tested for purity. It was found that the above mentioned procedure resulted in a population of 95–99% $T\mu^+$ cells. *$T\gamma^+$ and $T\mu, \gamma^-$ isolation*: The interphase fraction of the above mentioned gradient, consisting of the theophylline-sensitive cells, was rosetted with ox erythrocytes coated with rabbit anti-ox IgG[16]. The cell mixture was pelleted and incubated on ice for 20 min. Then the pellet was gently resuspended and layered on Ficoll–Isopaque ($\rho = 1.077$). After centrifugation (30 min, 1,000g) the pellet was freed of contaminating ox erythrocytes by NH_4Cl-induced lysis. The interphase (mainly consisting of $T\mu, \gamma^-$ cells) and the pellet fractions were tested for purity by determination of the number of $T\mu^+$ and $T\gamma^+$ cells present in the various fractions. Immediately after separation the pellet fraction contained 99% $T\gamma^+$ cells. After culturing overnight the FcγR could no longer be detected (ref. 3). Primed $T\mu^+$ cells were cultured with B cells, SE and when mentioned, with the various T-cell fractions. One representative experiment out of five is given.

* Assay system: 1.5 B cells + 5 SE (cell numbers × 10^6). † Unprimed, unselected, autologous T cells.

To characterise further the cell type receiving the signal from the primed $T\mu^+$ cells, we separated the unprimed, unselected T-cell suspension into $T\mu^+$, $T\gamma^+$, and T cells without detectable Fc receptors for IgM and IgG (therefore referred to as $T\mu, \gamma^-$ cells), by means of a number of isolation procedures (see Table 2 legend). We tested the cells for their potential inhibitory capacity by adding the different subsets separately to cultures of primed $T\mu^+$ cells and B cells, supplemented with a low dose of antigen. It is clear from the results listed in Table 2 that: (1) unprimed $T\mu^+$ cells apparently do not receive the signal provided by the primed $T\mu^+$ cells; (2) unprimed $T\gamma^+$ cells which can suppress the response when they are cultured with a high dose of antigen, do not suppress the response in this system when they are co-cultured with primed $T\mu^+$ cells and a low dose of antigen; (3) unprimed $T\mu, \gamma^-$ cells are capable of interacting with the primed $T\mu^+$ cells, resulting in an inhibition of the PFC response (results of five independent experiments). It is postulated that unprimed $T\mu, \gamma^-$ cells are capable of recognising the stage and intensity of the immune response by detecting or receiving signal(s) from primed T-helper cells, which can result in a feedback mechanism and thereby regulate the response.

The activity of the supernatants of the primed $T\mu^+$ cell cultures was examined for their capacity to induce feedback inhibition of the PFC response *in vitro* because of an increasing awareness of the fact that many T–T interactions do not seem to require contact of the relevant cells, but are mediated by soluble factors released from the participating cells[8,9]. As can be seen in Table 3, no inhibition of the PFC response could be obtained by the use of supernatants of primed $T\mu^+$ cells. On the contrary,

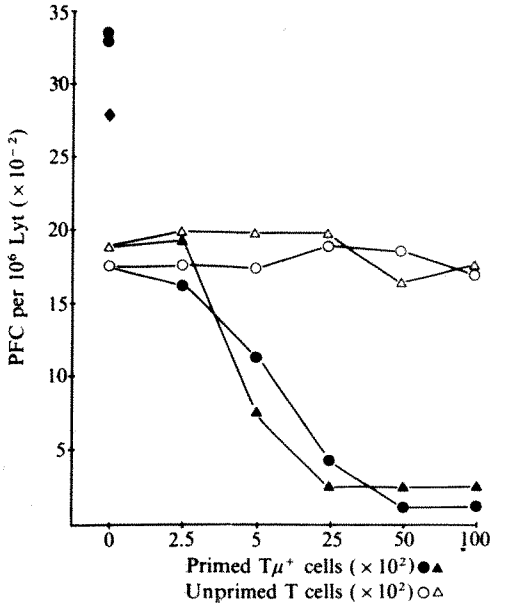

Fig. 1 Different numbers of primed $T\mu^+$ cells were added to a fixed number (3.5×10^6) of unprimed, unselected T cells (▲, ●; two donors). As a control the same numbers of unprimed, unselected T cells, derived from the two donors, were added to the same fixed number of unprimed, unselected T cells (△, ○;). ◆, ● represent the PFC responses when only primed $T\mu^+$ cells from the two donors were cultured with purified B cells. Every culture contained a low dose (5×10^6) of SE.

only a potentiating (helper) effect of the T-cell supernatant was observed.

We do not yet know whether this type of T–T interaction plays any physiological role in the regulation of the *in vivo* immune response in man. Cantor *et al.*[10] reported the absence of feedback suppression and a concomitant defect in the differentiation and/or function of T cells expressing the Lyt 123^+ phenotype in NZB mice. It was suggested[10] that the evidence provided by *in vitro* and *in vivo* experiments indicates that the absence of functional Lyt 123^+ cells and consequent lack of feedback suppression are somehow related to the development of autoimmune reactivity in NZB mice.

For the present we accept as a working hypothesis that a subset of T lymphocytes characterised as $T\mu, \gamma^-$ can be regarded as the human analogue of the murine Lyt 123^+ cell in the loop of a feedback inhibition mechanism of T-helper function. Therefore, we are investigating T-cell-mediated feedback suppression of the antigen-induced antibody response of peripheral leukocytes of patients suffering from systemic lupus erythematosus and myasthenia gravis. This investigation may yield information concerning the biological and clinical relevance of feedback inhibition of T-helper function in man. Moreover, it may to

Does lectin–receptor complex formation produce zones of restricted mobility within the membrane?

IT is well established that component lipids and proteins are mobile in the plane of the membrane[1,2]. This lateral mobility could have an important role in the transmission of signals through the membrane. For example, there is much evidence that aggregation of receptors induced by divalent antibodies or by chemical cross-linking can reproduce the biological action of the corresponding ligands[3–5]. It was shown recently that receptors for monovalent ligands like insulin and epidermal growth factor aggregate into patches on the cell surface after interaction with the corresponding hormone. Clustered receptors accumulate at coated regions of the membrane and become internalised in endocytic vesicles[6,7]. Aggregation is dependent on receptor occupancy by the active ligand[7]. Here we show that lateral mobility is also dependent on receptor occupancy. Our approach has been to compare the lateral mobilities of free and ligand-bound receptors using cultured cells placed in a steady electric field. This permits the measurement of lateral long-range (over the whole cell) mobility of the receptors with and

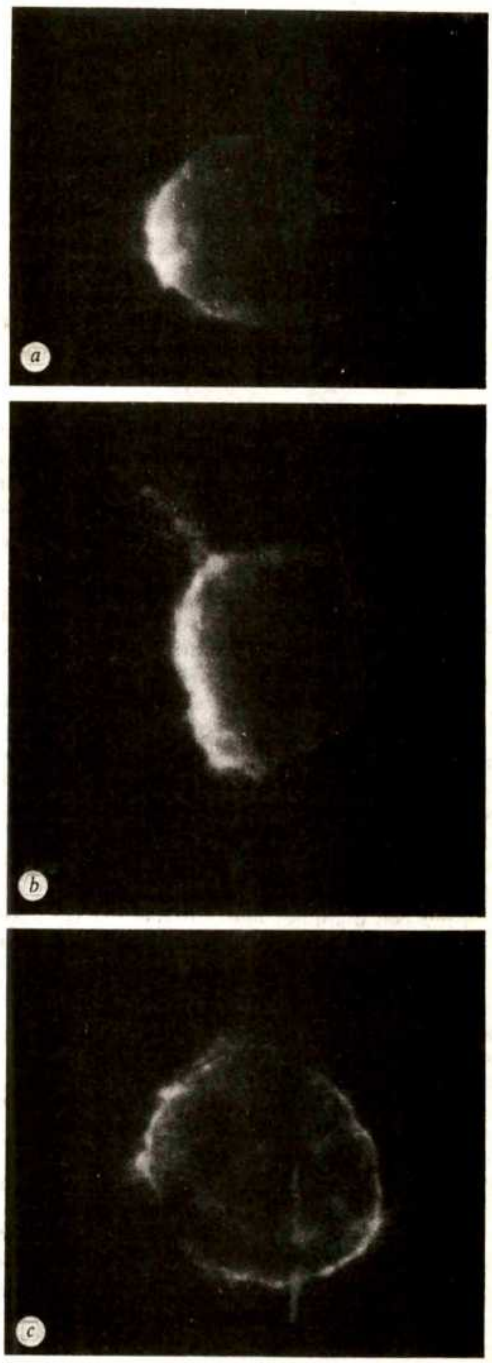

Fig. 1 TRITC-Con A-labelled NS-20 cells in a steady electric field observed by fluorescence microscopy. Conditions for a steady electric field were similar to those described by Poo *et al.*[8], Ag–AgCl electrodes, agar bridges and culture chamber made from microscope slide and pieces of no. 1 coverslides. After finding the 'stationary conditions' we used a uniform electric field of 12 V cm^{-1} for 15 min at room temperature (19 ± 2°C) in PBS. The cells (~100,000 cells for the chamber) were grown for 1 day in the chamber with F10 medium for the C_6 and with minimum essential medium for the NS-20 and 3T3 lines. All media were supplemented with 10% fetal serum and antibiotics. The conjugates TRITC (Mérieux) with Con A (Pharmacia) and ricin (molecular weight 120,000) were attached to Sephadex G-200 or Sepharose 4B, respectively, with subsequent elution of the sugars and passage through biobel P30. The cells were labelled with TRITC-labelled lectins at a concentration of 150 μg ml^{-1} for 10 min at 0–4°C before or after electrophoresis, and fixed with 2% paraformaldehyde (0–4°C for 10 min). Cells rapidly fixed with cold acetone (0–4°C, 30 s) had a similar distribution of receptors. *a*, *b*, The cells were exposed to an electric field before Con A–TRITC labelling and either fixed immediately (*a*) or were allowed to remain in MEM medium at room temperature for 35 min before fixation (*b*). *c*, The cells were exposed to a field after Con A–TRITC labelling. The photographs were taken using a Zeiss microscope equipped with Opak-Fluor veritcal illumination. Control cells not exposed to the electric field showed uniform ring staining (×2,124).

Table 1 Values of the diffusion constant (D) obtained by the electrophoretic (without ligand) and FPR methods

Cells	Electrophoresis ('free receptor') Con A D	Ricin D	FPR (ligand–receptor complex) Con A* D	$\%R$	Ricin D	$\%R$
NS-20	$2\text{–}3\times10^{-10}$	$2\text{–}3\times10^{-10}$	$6.0\pm0.5\times10^{-11}$	30% (20–50%)	$5.5\pm0.5\times10^{-11}$	~30%
C_6	$2\text{–}3\times10^{-10}$	2×10^{-10}			$6.0\pm0.5\times10^{-11}$	~40%
3T3	$1\text{–}2\times10^{-10}$					

In the photobleaching experiments carried out on dispersed Con A–receptor complexes, a Spectra-physic argon ion laser operating at <10 mW at 514 nm was used to bleach the spot and the same attenuated beam to excite fluorescence in the spot laser beam was passed into a Leitz microscope[9,10]. The laser beam diameter (3.4 μm) and the D values were determined with the calibration scan described by Axelrod *et al.*[12]. Coefficients expressed in $cm^2\ s^{-1}$; temperature of measurements, 19 ± 2°C; $\%R$, the per cent of the fractional fluorescence recovery.

*Also published values of Y.A.Z. *et al.*[10] obtained by the 'initial slope' calculations.

without the corresponding ligands[8]. We have compared this method with the dynamic method of fluorescence photobleaching recovery (FPR) which only permits measurement of the mobility of fluorescent ligand–receptor complexes in the range of the size of the laser beam diameter (~3 μm)[9–12]. We have studied the lateral mobility of concanavalin A (Con A) and ricin receptors from non-malignant fibroblasts 3T3 and malignant neuroblastoma NS-20 and C_6 glial cells with both techniques. Our results suggest that lectin–receptor formation results in the production of zones of restricted mobility in the membrane.

Results obtained by the 'electrophoretic' technique are shown in Figs 1 and 2. Application of an electric field to the extracellular compartment produced a migration of free Con A receptors towards the cellular membrane facing the positive pole (Fig. 1*a*). Removal of the electric field resulted in a redistribution of receptors over the whole cell surface. Determination of the time course of the redistribution (Fig. 2) enabled the lateral diffusion constant, D, to be calculated, using the equation $D=r^2/2\tau$, where r is the cell diameter and τ is the $1/e$ relaxation time. Values of D obtained in the various experimental situations tested are listed in Table 1. For the free receptors, all values were in the range $1\text{–}3\times10^{-10}\ cm^2\ s^{-1}$. These values are close to that obtained using the FPR technique on the pool of surface membrane proteins accessible to nonspecific labelling by fluorescein isothiocyanate[9,13]; they are also similar to values obtained for free Con A and surface antigen receptors[8,14]. In agreement with the conclusions of Edidin and Wei[14], the cytoskeletal elements do not seem to have any effect on the mobility of 'free' lectin receptors, as shown by experiments with drugs like cytochalasin B, colchicine and vinblastine. Finally, we note that the asymmetry observed after application of an electric field was less than 100% (Fig. 2). This reflects the fact that the cell population was heterogeneous with respect to the mobility of lectin receptors. For any given cell exhibiting receptor mobility the per cent asymmetry between the cellular borders facing the negative and positive poles was close to 100% (Fig. 1).

To measure the lateral mobility of ligand-bound receptors, free receptors were made to accumulate at one cell pole. The fluorescent lectins were then added immediately after removal of the electric field and the ligand-bound receptors were allowed to diffuse for various time intervals before the cells were fixed for microscopic examination. In all cases studied (Con A receptors from all cell lines used and ricin receptors from C_6 cells), no noticeable redistribution occurred within 35 min (Fig. 1*b*). We considered that this could mean the ligand–receptor complexes on the cells had become immobilised. To confirm this suggestion, the cells were treated with the ligand before electrophoresis, but there was no asymmetric redistribution of the receptors (Fig. 1*c*). This last result agrees with the observation of Poo *et al.*[8] for Con A receptors of frog muscle cells. In contrast, the use of the FPR technique to measure the lateral mobility of the lectin–lectin receptor complexes gave strikingly different results. The apparent diffusion constant ($5\text{–}6\times10^{-11}\ cm^2\ s^{-1}$, Table 1) was only 5 times less than the diffusion constant of the free receptors as determined by the electrophoretic technique. Values of D did not change during at least 2 h of measurement at room temperature in phosphate-buffered saline (PBS).

We can resolve this apparent discrepancy by suggesting that after interaction with the ligands the mobility of the receptors becomes restricted in specific regions. To investigate this suggestion, we carried out successive bleachings of tetramethylrhodamine isothiocyanate (TRITC)–Con A complexes of the same region of the membrane of NS-20 cells (Fig. 3). If the receptors have complete mobility, we would expect (after the third bleaching) ~90–100% recovery of fluorescence ($\%R$) (almost all the immobile molecules in the spot should be bleached with a bleaching parameter $K\simeq5$), but if receptor mobility is restricted fluoresence recovery should be substantially less than this. The results obtained (mean $\%R$ value after third bleaching $\simeq50\%$, nine experiments) support the suggestion that mobility of the receptors occurs in limited regions. Although the topology of the fluid stationary 'fields' in which these complexes move is unknown, the area of the fields seems to be of the order of the area of the laser beam ($\sim10\ \mu m^2$).

Cross-linking of receptors by multivalent lectins does not seem to be a major factor in the process of ligand-induced receptor immobilisation, because (1) receptor immobilisation could be induced using ricin R 60 (60,000 molecular weight form) which has only one binding site for sugar, and (2) the polyene antibiotic amphotericin B suppressed ligand-induced immobilisation of Con A and ricin receptors from C_6 and NS-20 cells[15]; amphotericin B did not affect lectin binding to receptors when added either before or after Con A or ricin and therefore cannot interfere with eventual receptor cross-linking.

We suggest that the appearance of these fields reflects a phase separation of membrane lipids which is triggered by ligand–receptor interaction[16–18]. There is evidence that a specifically

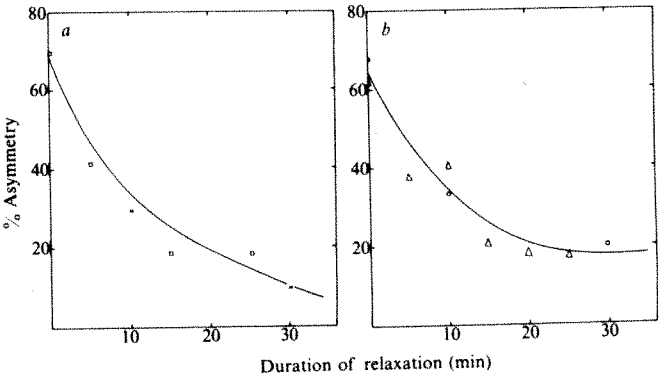

Fig. 2 Recovery of asymmetric distribution by relaxation. After removal of the field, the cells remained in the medium at room temperature for various periods of time before TRITC–lectin labelling and paraformaldehyde fixation. Per cent asymmetry $=(A-B/T)100\%$, where A and B are the number of cells showing asymmetric distribution of fluorescence towards the positive and negative poles, respectively, and T is the total number of cells examined. (Total number examined for each point was not less than 80.) In the case of long cells, we examined only cells which had their long axis aligned within 30° with respect to the direction perpendicular to the direction of the field. *a*, The relaxation of Con A receptors of NS-20 cells; the mean diameter of NS-20 cells was 14 ± 0.5 μm. *b*, The relaxation of Con A receptors of C_6 cells after treatment with colchicine, 5 $\mu g\ ml^{-1}(0)$ and 1 $\mu g\ ml^{-1}(x)$; the mean diameter of the C_6 cells was 16 ± 0.5 μm.

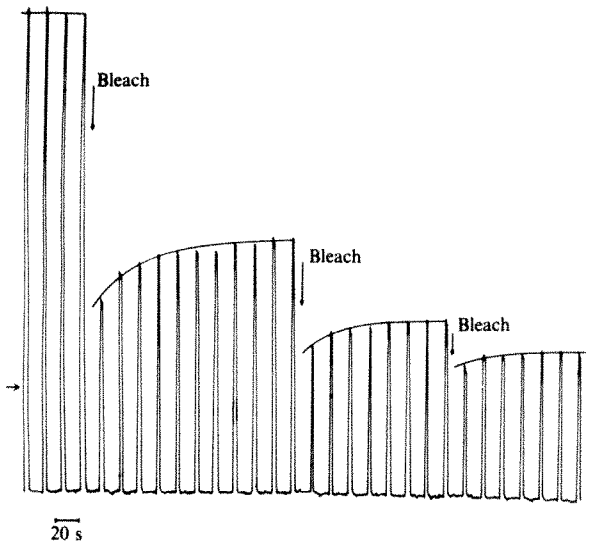

Fig. 3 Recorder trace of the fluorescence intensity of a succesively bleached spot on TRITC–Con A-labelled NS-20 cells. Values for the recovery of fluorescence after the 1st, 2nd and 3rd bleachings were 21%, 40% and 43%, respectively. The modulation was made with an optic-acoustic modulator (SORO). The intensity of fluoresence below the horizontal arrow corresponds to light scattering.

immobilised boundary layer of lipid surrounds the integral membrane proteins. Interaction of a membrane protein with a specific ligand might modify its interaction with surrounding lipids through conformational changes[18–20], or, as recently suggested by Hirata *et al.*[21] in the case of β-adrenergic receptors, through enzymatic conversion and catalysed 'flip flop' of membrane phospholipids in the vicinity of the receptor. In addition, changes in lipid fluidity after interaction of lectins with the membrane have been demonstrated[22]. A change in the lipid environment of lectin–lectin receptor complexes might facilitate their aggregation, leading to the occurrence of clusters surrounded by a more fluid zone of the membrane co-existing with the remaining pool of the membrane lipids and proteins. Our experimental results obtained with lectins at 20°C indicate that this state could correspond to a steady-state dynamic equilibrium.

We believe that the simplest way to explain this 'stationary phase' separation is to suggest a key role for cholesterol in the process. Cholesterol plays a critical part in creating a generally fluid phase, which would separate into liquid and gel phases if cholesterol were not present[23,24]. Cholesterol has a preference for some lipids (for example, lecithin) and a tendency for self-aggregation, but has no affinity for proteins[24]. Therefore, during microaggregation of receptors, cholesterol, which could have a preference for the new 'coat' lipids (like lecithin) of the receptors, could move from the 'common' membrane pool into the cavity created by the aggregated proteins, and the region external to the restriction zone could be the phase of the lipids with which the cholesterol has weak interactions (like phosphatidylethanolamine)[25] and which could be stabilised by Ca^{2+} ions[24]. This could enable restricted zones of the membrane to be in equilibrium with the remaining membrane pool of lipids and proteins. Suppression of ligand-induced receptor immobilisation by amphotericin B, which specifically interacts with cholesterol (refs 15, 26) supports the proposed interpretation.

(DTrp^6-Pro^9-NEt)-luteinising hormone-releasing factor inhibits follicular development in hypophysectomised rats

THE super-luteinising hormone-releasing factors (super-LRFs) are a group of synthetic analogues at least 100 times more potent than the native peptide *in vitro* and *in vivo*[1]. Several laboratories have demonstrated inhibitory effects of super-LRFs on ovulation, egg implantation, pregnancy, testicular weight and spermatogenesis[2–6]. Their proposed mechanisms of action involve some type of desensitisation of the pituitary to the highly potent LRF analogue and of the gonads to the gonadotropins released in large quantities by the super-LRF, in both target tissues through receptor down-regulation. Another, seemingly unlikely, explanation for the gonadal inhibitory effects of super-LRFs is that the synthetic peptide acts directly at the level of follicular ovarian tissues. Such a direct effect of super-LRF on the gonads has been suggested by the observation that large doses of LRF prevent cultured granulosa cells from aromatising androgens to oestrogens[7]. We now report that a super-LRF inhibits follicular development in hypophysectomised rats pretreated with pregnant mare serum gonadotropin.

Pregnant mare serum gonadotropin (PMSG) has predominantly FSH-like (follicular-stimulating hormone) activity and some LH-like (luteinising hormone) activity, and induces ovarian follicular development in intact as well as hypophysectomised immature rats[8]. Various doses of PMSG dissolved in 0.2 ml of 16% gelatin were given subcutaneously (s.c.) to 26-d-old female rats (from Hormone Assay, Chicago) approximately 24 h after hypophysectomy by the parapharyngeal route. Various amounts of the super-LRF, (DTrp^6-Pro^9-NEt)-luteinising hormone-releasing factor (pGlu-His-Trp-Ser-Tyr-DTrp-Leu-Arg-Pro-N.ethylamide) dissolved in 0.1 ml physiological saline were given s.c. at 8 a.m. and 5 p.m. daily for 3 d. The ovarian weights were recorded on day 31 as the endpoint. In some groups 20 IU of HCG (human chorionic gonadotropin) in 0.25 ml of physiological saline was given

0028-0836/79/330593—03$01.00

© Macmillan Journals Ltd 1979

intraperitoneally at 1.30 p.m. on day 30 and the incidence of ovulation was determined as reported previously[9]. The sella turcica of each rat was examined under magnification to determine whether the entire pituitary had been removed. The few rats in which pituitary fragments were found were not included in the results. The multiple comparison tests of Dunnett and Duncan for significance of differences were used for statistical evaluation of the experiments after an analysis of variance (computer program EXBIOL).

Administration of various doses of PMSG in 16% gelatin, a vehicle which delays absorption, produced a dose-dependent increase in ovarian weight (Table 1). Injection of the super-LRF inhibited the ovarian follicular development induced by PMSG. In rats treated with 50 IU PMSG, the minimum effective dose of super-LRF to prevent follicular induction was 0.08μg twice daily. A similar amount of native LRF or another analogue of LRF with D-amino acid substitutions [(DPhe^2-DPhe^6)-LRF] given in the same manner did not inhibit follicular development in animals pretreated with 50 IU PMSG, suggesting that the inhibition was not due to chronic injection of any decapeptide with or without a D-amino acid substitution. Experiments were also carried out to determine the responsiveness of these PMSG-primed follicles to HCG in animals concomitantly injected with the super-LRF nonapeptide: none of the animals treated with super-LRF ovulated, whereas treatment with HCG-PMSG without super-LRF resulted in the well known super-ovulation (Table 2).

These results clearly show that an analogue of the hypothalamic LRF, the super-agonist (DTrp^6-Pro^9-NEt)-LRF, has a direct effect on the ovary *in vivo*, inhibiting the follicular maturation normally induced by large doses of PMSG. Hseuh and Erickson have reported *in vitro* inhibitory effects of large doses of LRF on the aromatisation of androgens to oestrogens[7] by granulosa cells in monolayer cultures. Oestrogens are known to stimulate follicular maturation[10]; granulosa cells from medium-sized and small follicles do not grow or luteinise unless they are first primed with both FSH and LH[11], but oestrogens seem to facilitate stimulation of the mitosis of granulosa cells which is primarily responsible for follicle growth[10–12]. In the experiments reported here, no physiological responses to oestrogen secretion, such as extended uterine horns, increase in ovarian weight, and presence of proestrous vaginal smears and vaginal opening, were observed in super-LRF-treated rats whereas all these criteria were observed in the PMSG control animals. Thus, super-LRF itself seems to have adverse effects on steroidogenesis *in vivo* and consequently interferes with follicular development.

Super-LRF (20 μg per 0.1 ml per injection) was given s.c. at 8 a.m. and 5 p.m. for 3 d.

The inhibitory effect of super-LRFs has been suggested to be due to down-regulation of gonadotropin receptors in the gonads resulting from the extremely high level of gonadotropins induced by the super-LRFs[6,14]. Regulation of gonadotropin receptors in the gonad is highly sensitive to the circulating gonadotropin concentration, a marked loss of receptor sites occurring after treatment with exogenous gonadotropins. Through such a negative regulation of gonadotropin receptors and desensitisation of gonadal responses, super-LRFs would adversely affect ovarian steroidogenic function[6], ovulation[4] and growth of endocrine-dependent mammary tumours[15]. Indeed, Catt *et al.* have reported that the gonadotropin receptor content of the gonad exhibited delayed and protracted changes after single doses of super-LRF[14], and binding sites were totally abolished after treatment with 10 μg LRF. When the pituitary gland is removed as we report here, super-LRF must inhibit gonadal response to exogenous gonadotropin by acting directly at the gonadal level; this suggests that down-regulation of gonadotropin receptors may not be the only interpretation.

Judging from our observations that super-LRF directly inhibits follicular development, presumably due to interference with steroidogenesis, it is obvious that super-LRF may either bind to granulosa cells to alter the gonadotropin receptors or antagonise the subsequent secretory step of gonadotropin (PMSG) molecules by binding to the ovarian receptor site. Such a direct action of super-LRF on gonads and possibly on other reproductive organs, including the uterus, to explain its effects on egg implantation[6,16], would lead to the possibility of the local administration of super-LRF as a totally novel approach to contraceptive medication. Furthermore, we should not neglect the possibility that the inhibitory effects of super-LRFs on oestrogen-dependent mammary tumours could similarly be explained by or related to such a direct effect of the super-LRFs on the mammary tissues. Moreover, these observations and data reported by others[11–13] suggest that the gonad may contain and possibly secrete substances that might be included in a multi-step feedback system involving hypothalamic–pituitary peptides. Indeed, recent data from this laboratory have shown the presence in aqueous extracts from PMSG-stimulated ovaries, of both LRF-like and LRF-antagonistic activities, presumably of peptidic nature[17].

We thank Larry Trussell, Marte Leo and Ginny Page for technical assistance, Drs J. Rivier and N. Ling for providing the LRF analogues and Dr A. Parlow and the Rat Pituitary

Hormone Program of NIAMDD for PMSG. This work was supported by grants from NICHD (HD-09690-04), NIAMDD (AM-18811-04) and the William Randolph Hearst Foundation.

Endogenous opiates block dopamine inhibition of prolactin secretion *in vitro*

OPIATES stimulate prolactin secretion *in vivo*; plasma prolactin levels are increased by morphine administration in normal[1] and steroid-primed male rats[2], as well as in immature[3] and oestrogen-treated female rats[4]. Met-enkephalin and β-endorphin were also stimulatory[1–6] as were enkephalin analogues[3,7,8]. Naloxone or naltrexone, specific opiate antagonists, reduce basal prolactin levels when given alone[1,3,9], and block, at least partially, the effect of opiate agonists[1–4,7,8]. None of these drugs is active *in vitro* when tested alone on anterior pituitaries[3] or dispersed pituitary cells[2,4]. However, as we have previously shown in a preliminary experiment, the inhibitory effect of dopamine on prolactin secretion *in vitro* was antagonised by the addition of morphine to the incubation medium[10]. In the present work, we have attempted to clarify further the mode of interaction of opiates with prolactin secretion. We confirmed that morphine, Met-enkephalin and β-endorphin do not affect the spontaneous release of prolactin *in vitro*, but found that they suppress the inhibitory effect of dopamine on prolactin release. We have also characterised the specificity and the kinetics of this interaction.

To demonstrate the effect of these substances, paired control and experimental hemi-pituitaries of male rats (Wistar, Evic Seba) were incubated, under constant gassing (95% O_2, 5% CO_2), in medium 199 HEPES (Gypco) containing bacitracin (2×10^{-5} M) to prevent enzymatic degradation of peptides[11] and ascorbic acid (10^{-4} M) to protect dopamine against oxidation. Incubation time was 1 h following two 45-min preincubation periods. Both the incubation medium and extracts of the pituitary tissue were assayed for prolactin content against NIAMDD rat RP1 standard. Results are expressed as prolactin released into the medium as a percentage of prolactin content of the pituitary, as a good statistical correlation has been found between these two prolactin values[12].

Table 1 shows that morphine (10^{-6} M), Met-enkephalin (10^{-6} M), β-endorphin (5×10^{-7} M) or naloxone (10^{-6} M) alone did not affect basal prolactin secretion *in vitro*. As expected, dopamine (10^{-7} M) strongly inhibited the secretion of prolactin from hemipituitaries. The three opiates tested significantly

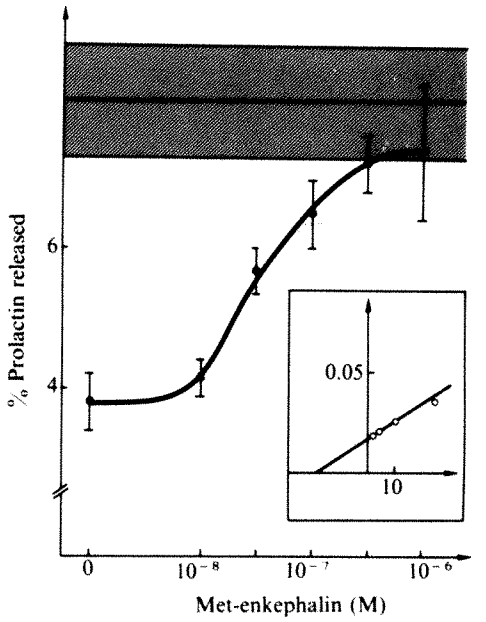

Fig. 1 Dose–response curve for the effect of Met-enkephalin on dopamine inhibition of prolactin release. The shaded area corresponds to the mean prolactin release of control pituitary ± s.e.m. Data are expressed as the percentage of the hormone content of the tissue released into the medium. Inset, Lineweaver–Burk plot of the data; ordinate: reciprocal of prolactin released; abscissa: reciprocal of Met-enkephalin concentration (μM^{-1}). Each value is the mean ± s.e.m. of 16 determinations. Average prolactin release of corresponding controls was 414 ± 36 ng ml^{-1}. In the presence of dopamine (10^{-7} M) increasing concentrations of Met-enkephalin progressively restored prolactin release to control levels.

blocked the dopamine inhibition. Their action could be antagonised by naloxone, which had no direct effect on the inhibition of prolactin secretion by the amine.

The effect of Met-enkephalin and β-endorphin on dopamine inhibition of prolactin release is dose dependent (Figs 1, 2). In the case of Met-enkephalin we were able to calculate kinetic constants for this interaction according to the method of Parker and Wand[13]. The apparent affinity was $4.1\pm0.8\times10^{-8}$ M. Complete reversal of dopamine inhibition occurred when 10^{-6}M Met-enkephalin was added to the incubation medium. The Hill constant calculated from the Met-enkaphalin inhibition curve ($n = 1.2\pm0.3$) was indicative of simple Michaelis–Menten kinetics. A similar result was obtained using the Lineweaver–Burk[14] plot of the data (Fig. 1), giving an apparent affinity of 4.5×10^{-8} M. Naloxone antagonised the effect of Met-enkephalin on dopamine inhibition in a dose-related manner (Table 2). The dopamine effect antagonised by 10^{-7} M Met-enkephalin was completely restored in the presence of 10^{-7} M naloxone. Another opiate antagonist, Mr 2266 (ref. 15), had a similar effect when added to the medium at a concentration of 10^{-7} M. In contrast, the optical isomer of this antagonist, Mr 2267 (ref. 15), was ineffective in the same conditions (Table 2).

We have thus confirmed previous data showing that incubation of pituitaries with opiates does not affect spontaneous prolactin release. This has led several authors to postulate that the morphinomimetic peptides may interact with prolactin regulating mechanisms at a higher level than the pituitary, possibly by modulating the turnover rate of tubero-infundibular dopaminergic neurones[16]. Although the present data do not exclude this hypothesis, they demonstrate that the prolactin response to opiates can be accounted for by a direct interaction of these substances with the effect of dopamine at the level of the pituitary prolactin cell.

Opiates do not affect dopamine receptors, as shown by ^{3}H-dihydroergocryptine binding to pituitary membrane preparations[17]; naloxone, morphine, Met-enkephalin and β-endorphin

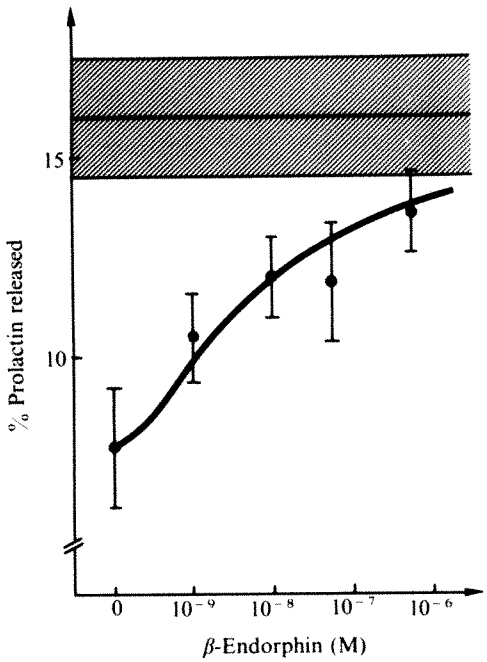

Fig. 2 Dose–response curve for the effect of β-endorphin on dopamine inhibition of prolactin release. Details as in Fig. 1 legend. Each value is the mean ±s.e.m. of eight determinations. Average prolactin release of corresponding controls was 709 ± 59 ng ml^{-1}.

do not affect ^{3}H-spiroperidol binding to striatal membranes[18]. Furthermore, in our experimental conditions, naloxone had no effect by itself on the dopamine-induced inhibition of prolactin release. We conclude from these results that two independent receptors mediate the action of dopamine and opiates on the pituitary.

Interactions between opiates and dopamine have already been described in other structures of the central nervous system[19,20]. In the case of the pituitary, reversal of the opiate effect by Mr 2266 or naloxone suggests that this interaction with dopamine is mediated by specific opiate receptors. In addition, as already reported for studies using different conditions[15,21], ineffectiveness of the optical isomer Mr 2267 to antagonise the action of Met-enkephalin demonstrates that the interaction of Mr 2266 with opiate receptors is stereospecific. Suppression of the opiate effect with low doses of antagonists also suggests that a specific opiate receptor is involved; interaction with other receptors only occurs with much higher concentrations of antagonists. For example, naloxone displaces ^{3}H-GABA binding in the cerebellum with an IC_{50} of 3×10^{-4}M (ref. 22). *In vivo* experiments using several enkephalin analogues also suggested that the effect of prolactin release is mediated by a specific opiate receptor[7,8].

Binding sites for morphinomimetic peptides have been identified in both the central and the peripheral nervous systems[23,24]. The affinity of various opiate antagonists depends on the structure on which the receptor is located. Opiate receptors have been identified in the pituitary[25], where the receptor density is much lower in the anterior lobe than in the neurohypophysis. The small proportion of prolactin cells in normal male pituitaries where, according to the present data, these receptors might be located, may account for the small number of receptors. The affinity of opiates for this receptor was lower than that calculated for central receptors which is in the range of 10^{-9} M. Our results agree with these data, for the apparent affinity for Met-enkephalin in our system is approximately 4×10^{-8} M.

Endogenous opiates, released either by the median eminence into the hypothalamo-hypophyseal portal system or by the pituitary into the general circulation, may be involved in the physiological regulation of prolactin secretion, as stress-induced prolactin release is blocked by naloxone[26,27] and naltrexone[9]. The opiate–dopamine interaction at the hypophyseal level which we have demonstrated may account for this physiological regulation.

We thank S. Ferri for Met-enkephalin, Endo for naloxone and Dr J. Jacob for Mr 2266 and Mr 2267. The work was supported by the Centre National de la Recherche Scientifique (A.E. and C.K.) and contract ATP No. 58 78 90 from the Institut National de la Santé et de la Recherche Médicale.

Table 1 Interaction of morphine, Met-enkephalin, β-endorphin and/or naloxone with basal and dopamine-inhibited release of prolactin from incubated hemi-pituitaries

	Naloxone	
	0	10^{-6} M
Control	15.1 ± 0.8	14.5 ± 0.7
Dopamine 10^{-7}M	8.1 ± 1.5*	9.0 ± 1.0*
Morphine 10^{-6}M	14.6 ± 0.9	
Dopamine + M	14.1 ± 1.4†	10.6 ± 1.0§
Met-enkephalin 10^{-6}M	14.4 ± 1.0	
Dopamine + Met-enkephalin	13.9 ± 1.6†	9.4 ± 1.1§
β-endorphin 5 + 10^{-7}M	14.8 ± 1.1	
Dopamine + β-endorphin	14.0 ± 1.0‡	9.2 ± 1.4§

Prolactin release is expressed as per cent of the hormone content of the tissue. Significance of the differences was assessed by variance analysis: *, highly significant inhibition as compared with controls; †, significant, or ‡, highly significant interaction of opiate agonists with dopamine inhibition; §, significant effect of naloxone as compared with corresponding dopamine + opiate agonist-treated hemi-pituitaries. Each value is the mean ± s.e.m. of eight determinations. Average prolactin release of corresponding controls was 722 ± 50 ng ml^{-1}.

Table 2 Dose dependence and stereospecificity of the effect of opiate antagonists on Met-enkephalin interaction with dopamine-inhibited prolactin release

Dopamine	Opiate antagonists	Met-enkephalin 0	Met-enkephalin 10^{-7} M
0	0	11.2 ± 1.1	—

10^{-7} M	Mr 2266 10^{-7} M	—	8.2 ± 0.9§
10^{-7} M	Mr 2267 10^{-7} M	—	11.6 ± 0.3

Increasing doses of naloxone restored dopamine (10^{-7} M) inhibition in the presence of Met-enkephalin (10^{-7} M). Another opiate antagonist, Mr 2266, was only effective at a concentration of 10^{-7} M, whereas its optical isomer Mr 2267 was inactive. Statistical data are indicated with the same symbols as in Table 1. Each value is the mean ±s.e.m. of eight determinations. Average prolactin release of corresponding controls was 393 ± 39 ng ml^{-1}.

Electrical properties of giant mitochondria studied with a double impalement technique

THE electrical properties of the membrane of giant mitochondria (4–10 μm in diameter) can be studied directly with microelectrodes. Tupper and Tedeschi[1–4] have studied mitochondria isolated from *Drosophila* (approximately 4 μm in diameter), and found a positive potential in the range of 5–15 mV and a specific resistance in the range of 1–4 Ω cm^2 (assuming no invaginations of the mitochondrial membrane). The potentials were not found to depend on metabolic state[2]. The microelectrodes were judged to be in the internal mitochondrial space from the fact that the potentials were osmotically sensitive (decreasing with osmotic swelling in a predictable manner). The positive potentials correlated with the distribution of carboxylic anions, which partition with a higher concentration inside the mitochondria. Furthermore, the potentials were collapsed by the addition of acetate[3,4], but not chloride[4] to the external medium. Presumably acetate enters and depolarises the potential. These observations further support the idea that the electrodes are in the inner mitochondrial space.

More recently, we have carried out studies with giant mitochondria from mice maintained on a diet containing cuprizone[5–8]. The isolated giant mitochondria seem to be in good physiological condition, as shown by the respiratory control of single isolated mitochondria[9], the P:O ratios of the mitochondrial suspensions[7,10], the direct bioassay of the ATP produced by single mitochondria or the ability to accumulate calcium phosphate[7,11]. The potentials were found to be in the range of 10–20 mV (positive inside) over a wide range of ionic composition of the medium. The specific resistances were found to be in the range of 1–5 Ω cm^2 (neglecting the membrane invaginations). The microelectrodes were in the inner mitrochondrial space as shown by the following criteria[6]. (1) In the presence of valinomycin, the potentials reversed in polarity and became sensitive to the K^+ concentration of the medium. Over a range of external K^+ concentrations, the measured potentials followed the Nernst equation approximately. (2) Almost identical results were obtained with mitochondria from which the external membrane was removed. (3) In a variety of conditions, advancing the electrode through the mitochondrion revealed a single potential, as long as the microelectrode had not emerged to the other side.

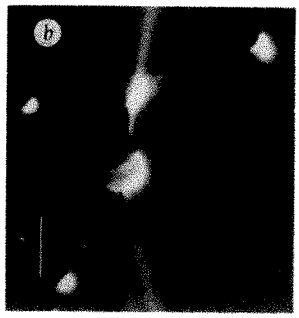

Fig. 1 *a*, Diagrammatic representation of the experimental design. 1 and 2 correspond to the electrodes used. The resistor shown is 10^7 or 10^8 Ω. The capacitor corresponds to 0–20 pF. *b*, A doubly impaled mitochondrion seen with Nomarski optics, water immersion objective (see ref. 6). The bar indicates 10 μm.

The measured positive potentials cannot be ascribed to artefacts involving the electrode tip, as the results were the same, regardless of whether the microelectrodes were loaded with KCl, NaCl (ref. 8) or potassium acetate (unpublished results).

Individual, intact or impaled mitochondria were found to be metabolically viable by two kinds of assays[7]. In one assay, the individual mitochondria were shown to exhibit granules in conditions in which mitochondria were known to accumulate massive amounts of calcium phosphate. The granulations were shown to correlate with increases in dry mass. They were interpreted to correspond to sites of accumulation of calcium phosphate. In another assay, individual mitochondria were shown to be capable of inducing the contraction of glycerinated myofibrils in close proximity to the mitochondrion (in some cases in the absence of other mitochondria[11]). Both the apparent

Table 1 Resistances after using the techniques represented in the figures

Experiments	Experimental design	Resistances (MΩ)
Series 1		
1	Single impalement (*b*)	3.7 ± 1.1 ($n = 12$)
2	Double impalement; measurement with the electrode delivering the current (*c*)	1.9 ± 0.8 ($n = 12$)
3	Double impalement; measurement with the electrode not delivering the current (*c*)	2.0 ± 1.1 ($n = 12$)
Series 2		
1	Single impalement (*b*)	3.8 ± 2.6 ($n = 6$)
2	Double impalement; measurement with electrode* delivering the current (*c*)	2.9 ± 2.5 ($n = 6$) 3.2 ± 2.0 ($n = 6$)
3	Double impalement; measurement with electrode* not delivering the current (*c*)	4.6 ± 2.4 ($n = 6$) 4.5 ± 2.2 ($n = 6$)

Values listed represent means ± s.d. The letters correspond to the diagram of Fig. 2. For series 1 the mitochondria were in 0.30 molal sucrose, 40 mM KCl, 1 mM $MgCl_2$, 3 mM sodium succinate, 2 mM potassium phosphate and 5 mM HEPES, *p*H 7.3. Excluding one value (−13 mV) for series 1, the membrane potentials were 1.2 ± 1.8 mV. For series 2, the mitochondria were in 0.30 molal sucrose, 10 mM KCl and 5 mM HEPES, *p*H 7.3. Only one membrane potential (+5 mV) was recorded in series 2.

* The induced potential was recorded from both electrodes.

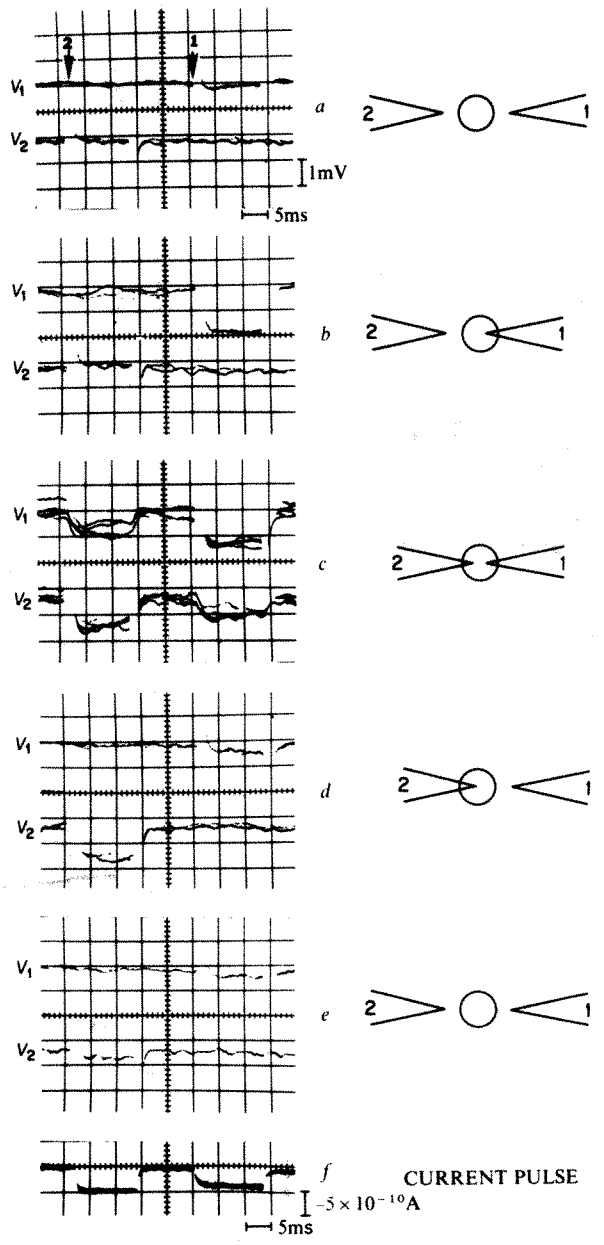

Fig. 2 The position of the electrodes and the electrical recording from a mitochondrion. The oscilloscope tracings are indicated on the left. The arrows indicate the start of the current pulses. The contrast has been reversed for ease in viewing. The corresponding location of the microelectrodes are indicated by the diagrams on the right. The microelectrodes are conventional micropipettes filled with 2 M KCl. The ground electrode consisted of a glass pipette containing 2 M KCl in 2% agar with a Ag–AgCl wire inside and connected to the virtual ground amplifier. Two electrometers (W-P Instruments, model M4A) with a minimum input resistance of 10^{10} Ω were used to pass current and simultaneously record potentials. The bath was held at virtual ground with the reference electrode by means of a current to voltage amplifier (Burr-Brown, operational amplifier, model 3308/12C) using a feedback resistor of either 10^7 or 10^8 Ω (wire wound, Victoreen). The output of this amplifier was monitored by a Tektonrix oscilloscope model 5110, using a 5A20N differential amplifier and a 5B10N time base (Tektronix). The output of electrometers was recorded with a Tektronix storage oscilloscope type R 564 B using a type 3A3 dual-trace differential amplifier and a type 2B67 time base. Current was injected using two type 161 Tektronix pulse generators controlled by a type 162 waveform generator. In this experiment negative current pulses of -4×10^{-10} A were delivered from electrode 1 and -3.5×10^{-10} A from electrode 2. The mitochondrion (8 μm in diameter) was in 0.3 molal sucrose, 10 mM KCl and 5 mM HEPES, *p*H 7.3 (≈25 °C).

accumulation of calcium phosphate and the contraction of the myofibrils were sensitive to the appropriate inhibitors or uncouplers of oxidative phosphorylation.

Despite the evidence summarised above, some investigators seem to harbour considerable reservation about the location of the microelectrodes. We have carried out a new series of experiments that bear on this question. Electrical tests of the location of microelectrodes in doubly impaled cells[12,13] or nuclei[14] have been in use for some time in electrophysiology. Characteristic voltage changes can be obtained with the delivery of current, depending on the location of the microelectrodes. In these experiments one microelectrode is used to deliver current and another to record potential. The experimental design allows one to distinguish the different possible locations of the microelectrodes from a record of the potential changes. In the case of cells, for example, one can distinguish whether both electrodes are outside the cell, both electrodes are pressed against the cells, (in the cases studied, the procedure actually produces deep invaginations where the electrodes are pressed against the cell surface (see Fig. 1 or ref. 12)), or both electrodes are inside the cell (see, for example, Fig. 4 of ref. 12). Only the latter experimental situation demonstrates a significant voltage response.

The microelectrodes and the pertinent circuits of our experiments are represented in Fig. 1*a*. The design allows recording and/or current delivery from either electrode. A doubly impaled mitochondrion is shown in Fig. 1*b*. The tracings correspond to oscilloscope records. Generally we used microelectrodes approximately 70 MΩ in tip resistance. In previous studies we have found that the results were independent of the tip resistance in the range of 10 to approximately 80 MΩ (refs 1 and 5). The records indicated in Fig. 2 were obtained after an initial balancing of the tip resistance. The impalements and withdrawals were sequential from *a* to *e*. *f* represents the current pulses, the first delivered from electrode 2 (-4×10^{-10} A), the second from electrode 1 (-3.5×10^{-10} A). In the oscilloscope record corresponding to the double impalement (*c*), five separate pulses have been superimposed. When both electrodes are in the external medium (*a* or *e*) there is no significant response from either electrode. We have found an absence of an induced potential at these current levels even when the electrodes are held at a distance well below 1 μm. With a single impalement (*b* and *d*), a response is obtained only from the impaling electrode. When both electrodes are in the mitochondrion (*c*) either electrode records the potential regardless of which delivers the current. Table 1 summarises two series of comparable experiments. The potentials across the mitochondrial membrane are in the legend to Table 1.

These experiments demonstrate that the two microelectrodes impaling a mitochondrion are in the same membrane-bounded space. Previous studies[6] have shown the same resistances in the presence and in the absence of the mitochondrial outer membrane, suggesting that in the present experiments the two electrodes are in the inner mitochondrial space.

These experiments and those previously presented[1-8] constitute evidence that the electrodes are in the mitochondrial matrix space and indicate the absence of a significant role of the membrane potential in the coupling of oxidation to phosphorylation. The details of a study on the membrane resistance of mitochondria using the double impalement technique will be presented elsewhere.

We thank C. Edwards, R. Rikmenspoel, C. L. Slayman and R. H. Adrian for helpful discussions, suggestions, and/or criticisms, and C. Edwards and J. Jacklet for use of some of their equipment. This work was aided by grant GM 23789 from NIH.

Use of Panamanian sea urchins to test the molecular clock

THE 'molecular clock' hypothesis of protein evolution holds that each protein changes at a constant rate, so that the degree of molecular divergence between two species is linearly related to the time for which their lineages have remained separate[1]. This assertion, however, has been challenged repeatedly by authors who discovered taxa and peptides in which the proposed uniformity of molecular evolution did not hold[2,3], who noted that biochemically and palaeontologically determined dates of separation between lineages conflicted[4,5], introduced tests that pointed to significant variation in the rates of evolution of the same proteins[6,7], or dismissed the hypothesis as a confusion of averages with constants[8]. Others have postulated that, although the same proteins evolve at different rates in different lineages, the average amount of molecular change over many proteins is sufficiently uniform to provide approximate dates for the splitting of two lines of descent[9,10]. Here I present evidence from sea urchins separated by the Isthmus of Panama which indicates that even this compromise position is not tenable.

It is important to resolve this issue for two reasons: first, the assumption of a linear relationship between time since separation and degree of molecular divergence has been used extensively to assign dates to the splitting of two lineages on the basis of biochemical evidence[11–15] and second, the proposed constancy of rate of amino acid substitution has frequently been cited as the strongest evidence for the neutral mutation theory, which maintains that the major cause of molecular evolution is random fixation of selectively neutral mutations[16–19]. In spite of one model that tries to account for the phenomenon in terms of natural selection[20], the most parsimonious theoretical basis for such a uniformity of rates remains that proposed by Kimura[17]. If most amino acid substitutions were neutral, their rate of fixation would equal the mutation rate, and it would be constant over long periods of time, provided that mutations are random events.

Because of the uncertainties involved in assigning fossils to either branch of a phylogenetic tree if they lie close to the node, rate determinations that use dates based on palaeontological evidence have been challenged by both proponents[1,14,15,21] and opponents[22] of the molecular clock. The best way to test the clock hypothesis is to assess the relative amounts of divergence within two or more groups, all of which split into new lines of descent at the same time[1]. Such a situation holds for the species pairs of Panama[11], where the emergence of the Isthmus in the Pliocene[23–25] fragmented the ranges of many marine species simultaneously. Populations thus separated have become known as geminate species.

There are seven genera of shallow water regular echinoids in the Caribbean, each of which is also represented in the eastern Pacific by populations that have been assigned a different specific name. On morphological grounds the Atlantic and eastern Pacific members of each genus are presumed to comprise geminate pairs[26]. I compared three pairs: *Diadema antillarum* (Caribbean (C)) and *Diadema mexicanum* (Pacific (P)); *Eucidaris tribuloides* (C) and *Eucidaris thouarsi* (P); *Echinometra lucunter* (C) and *Echinometra vanbrunti* (P). *Echinometra viridis*, a species sympatric with *E. lucunter*, was also included, because of the uncertainty as to which of the two is the true geminate of their Pacific counterpart. Enzymatic proteins were compared by electrophoresis; 18 presumptive loci (15 for *Eucidaris*) were sampled for two populations per species. Trans-isthmian divergence is measured relative to differentiation between conspecific population on the same coast. Such a calibration corrects for the possibility that electrophoretically undetected heterogeneity[27] may be unequally distributed among the genera or that the enzymes assayed are a nonrandom sample of the existing rates of molecular evolution. Differences are quantified by Nei's[28] standard genetic distance.

The clock hypothesis predicts that the extent of molecular differentiation in all pairs should be equivalent. Clearly, this is not the case (Table 1). Pacific populations of *Diadema* have diverged from their Atlantic counterparts no more than they have from populations on the same coast. *Eucidaris* and *Echinometra*, on the other hand, exhibit trans-isthmian distances 16 and 37 times greater than intraspecific ones. Even if we take the conservative stand that intraspecific distances are roughly the same for all genera, we find that the values of Nei's index for inter-oceanic comparisons of *Echinometra* are more than 20 times larger than those for *Diadema*. This conclusion holds whether *E. vanbrunti* is compared with either *E. lucunter* or *E. viridis*.

It is unlikely that the determined dissimilarities in divergence between geminates in the three genera are artefacts of the limited resolving power of electrophoresis. If 'hidden variation' in *Diadema* were 20 times lower than in *Echinometra*, we would expect the former also to exhibit lower values of intraspecific differentiation and heterozygosity. No such trend is apparent (Tables 1, 2).

The 20-fold difference between *Echinometra* and *Diadema* is also too great to be the result of different times of isolation during the gradual closing of the portals connecting the two oceans. All three genera produce planktonic larvae[29], and cessation of gene flow between their members must have been almost simultaneous. Furthermore, although the duration of the actual geological event is unknown, there is a range of estimates for the date of final completion of the land bridge between North and South America; the highest currently accepted estimate is 3.5–5.7 Myr ago[23,30], and the lowest about 2 Myr ago[24,25]. If we place the separation of *E. vanbrunti* from *E. lucunter* (or *E. viridis*) at this date and accept that divergence is linearly related to time, the analogous event in *Diadema* would have to be dated at 100,000 to 285,000 yr ago, when the land bridge between North and South America was continuous[25]. Similarly, the postulate that *Diadema* split at the time the Isthmus rose would require the speciation event in *Echinometra* to have occurred between the Eocene and the Cretaceous. Such an early origin of the extant species, whether due to the emergence of the Isthmus or some other geological occurrence, is unlikely as, despite a good echinoid fossil record, the genus is unknown before the Pliocene in the eastern Pacific[31] and the Oligocene in the Caribbean[32].

The disparity of the genetic distance values is also too great to be due to the stochastic variation allowed by proponents of the clock[1,19]. Nor can it be the result of generation time[33], as *Diadema* reaches sexual maturity sooner than *Eucidaris* or *Echinometra*[34].

The possibility that the extant species of *Echinometra* and *Eucidaris* may have speciated after the rise of the Isthmus from true geminates which subsequently became extinct would not redeem the clock hypothesis as molecular clocks are based on the assumption that divergence is dependent on the time two lineages have remained separate and not on the number of speciation events in each.

Different amounts of divergence between the species of *Diadema*, *Eucidaris* and *Echinometra* must, therefore, reflect

Values in parentheses are those obtained from an analysis restricted to the 12 loci common to all three genera. Electrophoresis was carried out on 11% starch for all enzymes except amylase; 7% acrylamide gels were used for the latter. Standard histochemical tehcniques were used for staining. Collections were made at: Fort Randolph, Canal Zone (*D. antillarum*); Bocas del Toro, Republic of Panama (*D. antillarum, E. tribuloides, E. viridis, E. lucunter*); Maria Chiquita, Republic of Panama (*E. lucunter*); San Blas Islands, Republic of Panama (*E. viridis, E. tribuloides*); Isla Uraba, Bay of Panama (*D. mexicanum*); Punta Paitilla, Bay of Panama (*E. thouarsi, E. vantrunti*); Isla Uva, Gulf of Chiriqui (*D. mexicanum, E. thouarsi, E. vanbrunti*). Loci examined for each genus were: *Diadema*: phosphoglucomutase (PGM): PGM-1, PGM-2; phosphoglucose isomerase (PGI); hexokinase (HK); peptidases (Pep): Pep-1, Pep-2, mannose-6-phosphate isomerase (M6PI); NAD-dependent malate dehydrogenase (MDH): MDH-1, MDH-2, triose phosphate isomerase (TPI); leucine amino peptidase (LAP); amylase (Am): Am-1, Am-2; tetrazolium oxidase (TO); glucose-6-phosphate dehydrogenase (G6PDH); xanthine dehydrogenase (XDH); esterases (Est): Est-1, Est-2. *Echinometra*: PGM-1, PGM-2, PGI, HK, Pep-1, Pep-2, M6PI, MDH-1, MDH-2, TPI, Am-1, Am-2, Am-3, TO, G6PDH, XDH, LAP-1, LAP-2. *Eucidaris*: PGM-1, PGI, HK, Pep-1, M6PI, MDH-1, TPI, LAP, AM-1, AM-2, TO, XDH, Est-1, Est-2, Est-3. Sample sizes per locus (number of alleles) ranged from 36 to 134 (most above 90), with one, PGM-1, *E. thouarsi*, Isla Uva, represented by only six. See ref 39 for details of the methods.

dissimilar rates of protein differentiation, and argue against the molecular clock hypothesis. West (in preparation) has reached the same conclusion on the basis of allozymic differentiation in four geminate species pairs of Panamian crabs.

The results could still be compatible with the neutral mutation theory if they reflected differences between the genera in mutation rates or in histories of population size. Both these postulates, however, would conflict with the predictions of the same theory regarding the heterozygosity values of the populations involved.

Many models[35-37] predict that variability of neutral alleles is a function of the mutation rate. If *Diadema* has a mutation rate 20 times lower than *Echinometra*, it should also display less gene diversity. This is not the case (Table 2). Average heterozygosity values are very similar in populations belonging to the two genera. A severe population restriction more recent than 10^7 generations ago in *Echinometra* but not *Diadema* could also result in dissimilar rates of divergence compatible with the neutral mutation theory[38]. However, if the higher rates of divergence in *Echimometra* were the result of such a bottleneck, neutral theory would expect its populations in at least one ocean to exhibit lower levels of heterozygosity than those of *Diadema*[38]. This is not so (Table 2).

I conclude that the molecular clock hypothesis does not hold for the Panamian echinoids, and that their unequal rates of protein divergence with similar levels of heterozygosity are in direct opposition to the predictions of at least one model based on the neutral mutation theory. The most plausible explanation for the observed discrepancies is that molecules have been evolving under the influence of natural selection.

I thank G. Maduro, and Carolyn and Charles Glendening for technical assistance, R. Harrison, W. D. Hartman, J. A. W. Kirsch, J. R. Powell, S. Rachootin, D. Simanek and W. J. Tabachnick for comments on the manuscript, the Smithsonian Tropical Research Institute for the use of its facilities and research vessel, and particularly D. A. West for his help. This was supported by NSF grant DEB 76-02607, a Smithsonian Pre-doctoral Fellowship and a Noble Fellowship from STRI.

Placental alkaline phosphatase in Hominidae

HUMAN placental alkaline phosphatase has several unique properties. It is stable to heating at 65 °C (ref. 1), is immunochemically distinct from the isoenzymes in other adult organs[2,3], and has a large number of allelic variants[4–6], with a 'degree of heterozygosity' much larger than that of any other human enzyme studied to date[7]. If placental phosphatase is specific to fetal development, it would be logical to expect that a similar isoenzyme would be present during fetal development in other mammalian species. This is not the case, however, as several species, including rhesus monkey, African green monkey and baboon, do not have in their placentae an isoenzyme which resembles human placental phosphatase[8]. The presence of the placental isoenzyme in humans therefore seems to be a late evolutionary event. To determine the species specificity of this enzyme, we have used the criteria which distinguish the human placental isoenzyme, including inhibition by 5 mM L-phenylalanine[1] and insensitivity to inhibition by 0.1 mM bromotetramisole[9], to compare the enzymes in species closely related to man. We report here that of the species studied, only the chimpanzee and orangutan have an isoenzyme resembling that in humans.

The enzyme assay used was as previously described[10]. Placental homogenates using full-term placentae were prepared using 3 ml of 0.01 M Tris-HCl, *p*H 7.6, per g of tissue. Antiserum used was prepared as described previously[11] and was obtained 10 weeks after primary immunisation. Enzyme staining was also as previously described[11].

Table 1 summarises the properties of the primate placental phosphatases. The enzymes from human, chimpanzee and orangutan placentae are similar in their activity, sensitivity to bromotetramisole and insensitivity to heat inactivation. The chimpanzee and human placental phosphatases are also very similar in their sensitivity to L-phenylalanine inhibition, the orangutan enzyme, less so.

The gorilla and spider monkey placental phosphatases were less active than those of the other three by two to three orders of magnitude, and were more sensitive to inhibition by bromo-

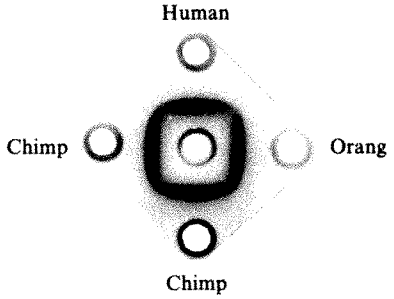

Fig. 1 Double diffusion of human, chimpanzee (chimp) and Bornean orangutan (orang) placental alkaline phosphatases against monospecific antiserum raised against human placental phosphatase. Each enzyme, 0.012 units, was placed into the appropriate wells and 10 μl of 1 : 8 diluted antiserum was placed in the centre well. Diffusion was allowed to proceed for 3 days at 37 °C, after which the gel was exhaustively washed with 0.01 M Tris-buffered saline, *p*H 7.6, and stained for enzyme.

Table 1 Properties of alkaline phosphatases from several primates

	Activity (μmol min^{-1} ml^{-1})	Per cent inactivation by: Br-tet	L-Phe	Heat
Human	5.7	32±7	77±5	6±5
Chimpanzee	8.0	30±7	70±2	6±1
Lowland gorilla	0.01	80±2	31±7	77±4
Orangutan	2.7	35±12	45±10	15±3
Spider monkey	0.04	56±3	30±6	62±4

Br-tet, 0.1 mM bromotetramisole (Aldrich); L-Phe, 5.0 mM L-phenylalanine (Sigma); heat, heating for 10 min at 65 °C.

tetramisole, less sensitive to L-phenylalanine inhibition and markedly more readily inactivated by heat. The orangutan placental phosphatase was the least sensitive to L-phenylalanine inhibition.

Note that 20% of the lowland gorilla placental phosphatase and 38% of the spider monkey enzyme remained after heating for 10 min at 65 °C. In both cases this remaining activity was three orders of magnitude less than the amount of heat-stable enzyme found in the human, chimpanzee and orangutan placentae. Figure 1 shows the results of comparing the three related placentae by double diffusion. The absence of 'spurs' indicates that these enzymes are similar in their immunochemical structure.

The considerable difference of the human, chimpanzee and orangutan placental phosphatases from those of baboon, rhesus monkey, African green monkey and spider monkey suggests that the occurrence of the type and/or amount of alkaline phosphatase found in human placentae is a relatively late event in primate evolution. The apparent absence of a similar isoenzyme in lowland gorillas is surprising, as there is no evidence[12] for a divergence of this species from the line of man's descent after the orangutan. However, this placenta was only a single sample, and was taken from a mother with abruptio placentae and recent fetal death. The content of luteinising hormone in the placenta and its histology were normal.

The existence of a null allele for human placental phosphatase has been suggested[13]. The very low activity of the enzyme in the lowland gorilla could be due to the infant being homozygous for this null allele. Alternatively, there could be an alteration in the regulation of synthesis of the enzyme in this species, so that there is very little of this enzyme present in the species as a whole. Examination of other gorilla placentae should establish which of these possibilities is correct.

By comparing the specific activity of pure placental phosphatase with that of 150,000g max pellets of placental extracts, we have estimated that on average, 1% of the membrane protein of human placentae is alkaline phosphatase. The very low activity in rhesus, African green, baboon and spider monkeys and possibly gorillas, and the apparent biochemical distinction of the enzymes in these species is extremely interesting. No other human tissue has been found to have an enzyme which does not occur in the corresponding tissue in monkeys. The presence of this enzyme in such high concentrations in the human placenta is therefore species specific. This may account for the unusually high degree of heterozygosity at this locus[7] and the apparent role of several genetic variants in prenatal selection[14,15]. If the expression of the enzyme during human fetal development is a late evolutionary event, then selection of phenotypes could still be much more active than that of other enzymes whose organ-specific function has become specialised over a longer period of evolution.

The similarity of orangutan, chimpanzee and human placental phosphatase by double diffusion is interesting. It suggests that, despite the occurrence of this enzyme late in primate evolution, the gene coding for it is similar in all three species. It is likely that an enzyme similar to human, chimpanzee and orangutan placental alkaline phosphate is normally present in an organ(s) other than the placenta (or at much lower concentrations in the placenta), and that its presence in the placenta is the species-specific event. This could have occurred after a gene duplication or by de-repression of a regulator gene in the placenta[16].

The production of significant amounts of placental-type alkaline phosphatase, the so-called 'Regan isoenzyme'[17], and variants of this enzyme[18,19] in some cancer patients, has been interpreted as being due to de-repression of a fetus-specific gene product[20]. If the gene coding for placental phosphatase is in fact expressed in some other as yet unidentified organ, then the occurrence of the enzyme in this organ pre-dates its occurrence in the placenta. The production of placental-type alkaline phosphatase by the placenta and certain tumours may therefore be a coincidence, not the expression of fetal genes in neoplasia. This hypothesis might be tested by investigating the presence of placental-type alkaline phosphatase in non-neoplastic human tissues and studying these same tissues in non-human primates.

In view of the apparent species specificity of the placental phosphatase, it would be interesting to develop a complete catalogue of the occurrence of this enzyme type in non-human primates. It is possible that this might reveal a new biochemical aspect of primate evolution, especially if the function of this enzyme is determined.

Human placental alkaline phosphatase differs from that of other species

AT LEAST three gene loci seem to be involved in determining the various forms of human alkaline phosphatase (ALP)—one coding for the placental form of the enzyme, at least one coding for the intestinal forms, and at least one for the liver, bone and kidney forms[1,2]. These three classes of human alkaline phosphatase can be distinguished from one another by their

	Liver	2.41	33.73	29.95

The tissues were kept frozen at −20 °C until extracted. Aqueous solutions of the enzyme were obtained by extracting the tissue in the presence of *n*-butanol as previously described[1]. Assays were carried out using *p*-nitrophenyl phosphate (5.0 mM) as substrate in a diethanolamine buffer 1.0 M *p*H 9.85, containing 0.28 M NaCl and 0.5 mM $MgCl_2$. The inhibitors were added to the reaction mixture to produce final concentrations of 1, 2.5, 5, 10 and 20 mM. In the case of human placenta with PGG, assays were also carried out in the presence of 0.2 and 0.5 mM of this inhibitor. The reactions were run for up to 30 min at 30 °C and stopped by the addition of a volume of 1 M phosphate buffer, *p*H 9.8, equal to the volume of the reaction mixture. Absorbance was read at 405 nm. Degree of inhibition was expressed as percentage of the original activity remaining in the presence of a given concentration of inhibitor. Two or more determinations were made on each sample at each inhibitor concentration and in some cases samples from different individuals of the same species were examined. The average value was used in the subsequent calculations. Estimates of $[I]_{50}$ were obtained by calculating the least-squares regression of (100/per cent activity remaining) on concentration of inhibitor, [I], and determining from this the concentration of inhibitor required to give 50% inhibition (see Fig. 1 legend).

behaviour with certain inhibitors, their thermostabilities and their electrophoretic and immunological characteristics. Recent studies have shown that in the dog, the ALP present in placenta closely resembles that in liver, and that these enzymes are very similar to the ALP present in human liver but different from the ALP present in human placenta[3,4]. It has also been reported that human placental ALP differs from other mammalian placental ALPs in certain respects (for example, sensitivity to L-phenylalanine inhibition)[5,6]. In view of these results we have examined some of the characteristics known to distinguish human placental and human liver ALPs, in the liver and placental ALPs from a series of mammalian species. The species from which both tissues were obtained included rodents, carnivores, ungulates and one primate (rhesus). We report here that the properties of human placental ALP differ from those of human liver ALP, whereas in the other species studied, placental and liver ALPs show similar properties.

Particularly sharp discrimination between human liver and placental ALPs can be achieved using L-homoarginine (HA), L-phenylalanine (Phe) and L-phenylalanylglycylglycine (PGG) as inhibitors[1]. HA produces marked inhibition of liver ALP at concentrations which produce only slight inhibition of placental ALP[7]. In contrast, Phe and PGG produce marked inhibition of placental ALP at concentrations which produce only slight inhibition of liver ALP[1,8]. This combination of inhibitors also distinguishes intestinal ALP from both liver and placental ALP[1,9]. The percentage activity remaining in the presence of various concentrations (1–20 mM) of each of these inhibitors was determined for the different liver and placental ALPs of the various animal species. As a general rule the reciprocal of the reaction velocity of an enzyme may be expected to vary linearly with the concentration of an inhibitor[10,11]. This was found to be the case for the various ALPs with these particular inhibitors. Some typical plots are shown in Fig. 1. The greater the slope of the regression line, the greater the degree of inhibition produced by the particular inhibitor. The least-squares regression was therefore calculated for each set of data and from this the concentration of inhibitor required to produce 50% inhibition of the enzyme, $[I]_{50}$, was estimated. These estimates are given in Table 1 for the liver and placental ALPs of each species with each of the inhibitors.

It is apparent that for each of the inhibitors the estimated $[I]_{50}$ for human placenta is quite different from the estimated $[I]_{50}$ values for any of the placentas from the other species. Table 2 gives the means of the $[I]_{50}$ estimates for the series of non-human placental ALPs and for the liver ALPs. They are in close agreement. A paired *t*-test gives no evidence for significant differences between $[I]_{50}$ placental ALP and $[I]_{50}$ liver ALP in any of the species (HA, $t = 0.68$, d.f. = 9, $P > 0.5$; Phe, $t = 1.28$, d.f. = 9, $P > 0.2$; PGG, $t = 0.91$, d.f. = 9, $P > 0.2$). Note that the $[I]_{50}$ values for human liver ALP for each of the inhibitors do not deviate significantly from the mean $[I]_{50}$ values for placenta or liver ALPs of the other species. In contrast, the $[I]_{50}$ for human placental ALP with HA is about 30 times greater than the mean $[I]_{50}$ for the liver and placental ALPs of the other species; and the mean $[I]_{50}$ values for the liver and placental ALPs of the other species with Phe and PGG are about 30 times and 300 times greater, respectively, than the corresponding $[I]_{50}$ values for human placental ALP. An analysis of variance of the placental and liver ALP $[I]_{50}$ values was carried out to see whether there were significant differences between the non-human species. However, no significant heterogeneity was detected (HA, $F = 1.03$, d.f. = 9, 10, $P > 0.25$; Phe, $F = 0.41$, d.f. = 9, 10, $P > 0.75$; PGG, $F = 1.91$, d.f. = 9, 10, $P > 0.10$).

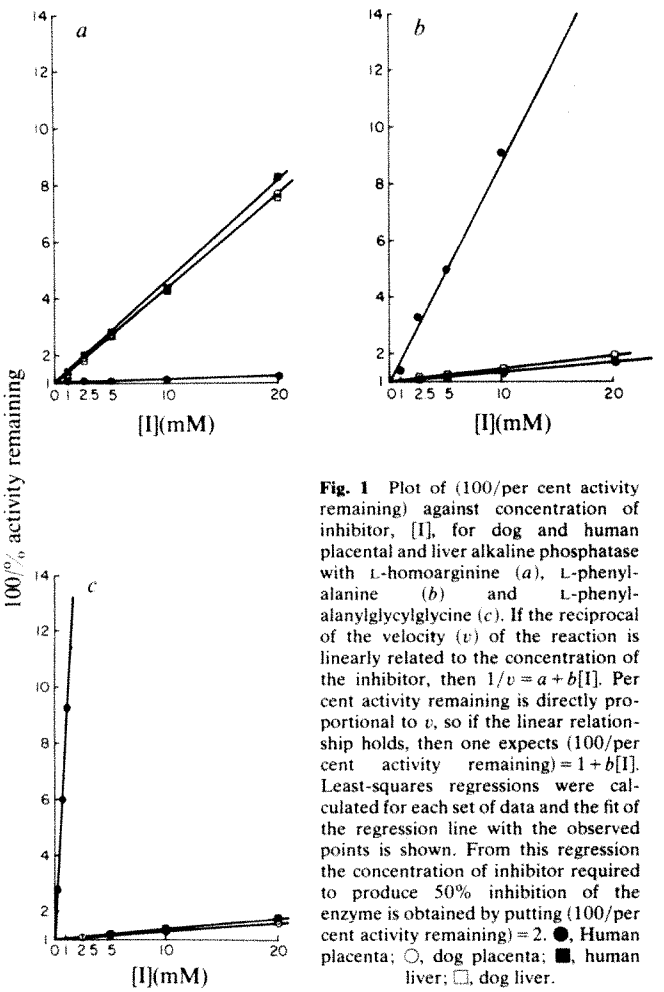

Fig. 1 Plot of (100/per cent activity remaining) against concentration of inhibitor, [I], for dog and human placental and liver alkaline phosphatase with L-homoarginine (*a*), L-phenylalanine (*b*) and L-phenylalanylglycylglycine (*c*). If the reciprocal of the velocity (v) of the reaction is linearly related to the concentration of the inhibitor, then $1/v = a + b[I]$. Per cent activity remaining is directly proportional to v, so if the linear relationship holds, then one expects (100/per cent activity remaining) $= 1 + b[I]$. Least-squares regressions were calculated for each set of data and the fit of the regression line with the observed points is shown. From this regression the concentration of inhibitor required to produce 50% inhibition of the enzyme is obtained by putting (100/per cent activity remaining) = 2. ●, Human placenta; ○, dog placenta; ■, human liver; □, dog liver.

Thus, the data suggest that the structures of the binding site(s) for HA, Phe and PGG must be identical or at least very similar in the placental and liver ALPs of these various species and also in human liver ALP. However, the structure of the binding site(s) for these inhibitors in human placental ALP is presumably quite different.

Table 2 Means and standard deviations of estimated $[I]_{50}$ values for various inhibitors for human and non-human placental and liver alkaline phosphatase

			$[I]_{50}$ (mM)					
			HA		Phe		PGG	
		No. of species	Mean	s.d.	Mean	s.d.	Mean	s.d.
Man	Placenta	1	62.88	—	1.13	—	0.09	—
	Liver	1	2.83	—	28.62	—	27.44	—
Mammals (excluding man)	Placenta	10	2.71	0.21	35.92	8.03	31.30	4.21
	Liver	10	2.82	0.47	31.20	5.80	32.76	4.40

$[I]_{50}$ values for HA, Phe and PGG are from 10 different mammalian species compared with the corresponding values for the human enzymes.

Human placental ALP is remarkably thermostable[12]. It may be heated at 65 °C for more than 1 h with little or no loss of activity. In contrast, human liver ALP is rapidly destroyed in these conditions. The thermostabilities of the various animal liver and placental ALPs were therefore determined. Each of the samples was heated at 65 °C and also at 56 °C for different times up to 30 min and the residual activities determined. In each case the regression of the (log percentage activity remaining) on time was calculated, and from this an estimate of the time required to produce 50% inactivation of the enzyme, T_{50}, was obtained. The results (Table 3) indicate that the various non-human placental and liver ALPs are relatively thermolabile and indeed similar to human liver ALP in this respect. The mean T_{50} values for placental and liver ALPs of the non-human species (Table 4) are in close agreement. A paired *t*-test showed no evidence for significant differences between the placental or liver ALP T_{50} values in any of the species. The human liver ALP T_{50} value does not deviate significantly from either the placental or liver ALP mean T_{50} values. Human placental ALP is, of course, quite stable in these conditions. An analysis of variance of the T_{50} values for the non-human placental and liver ALPs was carried out to see whether there was evidence for significant differences between the species. Significant heterogeneity was indeed detected (56 °C, $F = 3.29$, d.f. = 9, 10, $0.01 < P < 0.05$; 65 °C, $F = 7.29$, d.f. = 9, 10, $P < 0.01$). Such thermolability differences presumably reflect differences in the overall molecular structures of the ALPs in the different species.

Table 3 Time required to produce 50% inactivation of alkaline phosphatase in placenta and liver of various mammals

		56 °C T_{50} (min)	65 °C T_{50} (min)
Man	Placenta	Stable	Stable
	Liver	8.2	1.05
Dog	Placenta	23.1	1.20
	Liver	14.2	1.31
Mouse	Placenta	2.3	0.58
	Liver	5.8	0.80
Rat	Placenta	2.2	0.42
	Liver	5.0	0.84
Sheep	Placenta	10.8	0.52
	Liver	9.0	0.35
Cow	Placenta	10.9	1.04
	Liver	16.0	1.32
Pig	Placenta	9.7	0.91
	Liver	3.5	0.65
Guinea pig	Placenta	6.6	0.97
	Liver	6.6	0.92
Rhesus	Placenta	8.2	0.76
	Liver	18.7	0.45
Hamster	Placenta	4.4	0.21
	Liver	7.9	0.32
Cat	Placenta	12.3	0.67
	Liver	18.2	0.60

Thermal inactivations were carried out at 56 °C and 65 °C on tissue extracts dialysed against 10.0 mM Tris-HCl, *p*H 7.5, containing 2 mM $MgCl_2$. The samples (0.2 ml) were placed in capped plastic tubes (Falcon 2038) and heated in a waterbath for 5, 10, 15, 20 or 30 min at 56 °C and for 1, 2.5, 5, 10, 15 or 20 min at 65 °C. At the end of each period the tube was immediately placed in an ice bath where an unheated control had been kept for the same period. Thermal inactivation was expressed as percentage of original activity remaining after a given time at the particular temperature. Two or more determinations were made on each sample at each period and in some cases samples from different individuals of the same species were examined. The average values were used in subsequent calculations. Estimates of T_{50} were obtained by calculating the least-squares regression of (log per cent activity remaining) on time and determining from this the time required for 50% inactivation.

Table 4 Means and standard deviations of estimated T_{50} values for human and non-human placental and liver alkaline phosphatase

		56 °C T_{50} (min)		65 °C T_{50} (min)	
Man	Placenta	Stable	—	Stable	—
	Liver	8.2	—	1.05	—
Mammals (excluding man)	Placenta	9.1	6.1	0.73	0.31
	Liver	10.5	5.7	0.76	0.36

The T_{50} values at 56 °C and 65 °C for placental and liver alkaline phosphatases were from 10 different mammalian species compared with the corresponding values for the human enzymes.

The results show that in terms of the inhibition and thermostability characteristics studied here, placental and liver ALPs are indistinguishable in each of these mammalian species other than man. The data suggest that the same gene locus is being expressed in liver and placenta of the various species and that this locus corresponds to the ALP locus being expressed in human liver. It is, however, presumably different from the ALP locus expressed in human placenta.

These findings are of evolutionary interest. It has been suggested that the liver/bone/kidney, intestinal, and in man, placental, ALPs represent a so-called multilocus enzyme system, the loci coding for these enzymes having been derived in the course of evolution from a common ancestral gene as a result of successive gene duplications[4,13]. Mutations occurring in the genes subsequent to the duplications would have led to some divergence in their base sequences, and thus to characteristic differences in the properties of the ALPs they now determine. If this is correct, a plausible interpretation of the data is that the gene duplication giving rise to the human placental ALP gene locus was a relatively late evolutionary event which occurred subsequent to the divergence of the evolutionary lineage leading to man from the various lineages leading to most other mammalian species, including rhesus, an Old World monkey. An alternative hypothesis would be that a gene locus corresponding to the human placental ALP locus does exist in these other mammalian species but is not expressed in their placentas, so that the late evolutionary event would have involved its derepression or activation accompanied by repression of the locus coding for liver ALP. This seems a less economical hypothesis. However, eventually it should be possible to distinguish critically between the two hypotheses, by direct studies of the genes at the DNA level using the newly emerging methods of DNA analysis, such as restriction endonuclease mapping. The apparently late evolutionary appearance of the human placental ALP locus is also of interest in connection with the fact that human placental ALP, unlike the intestinal and liver ALPs, is genetically highly polymorphic.

α-Globin gene organisation in blacks precludes the severe form of α-thalassaemia

IN most human populations, the α-globin structural gene loci are duplicated so that each diploid cell contains four copies of α-globin genes[1–3]. In α-thalassaemia, a hereditary disorder of α-globin chain synthesis, the most common molecular lesion is due to the deletion of the α-globin genes[4–7]. In the Asian population, four main α-thalassaemia syndromes of increasing clinical severity are recognised: (1) the silent carrier state (α-thalassaemia-2) with no clinical manifestation; (2) α-thalassaemia trait (α-thalassaemia-1), characterised by microcytic red blood cells but little or no anaemia; (3) haemoglobin-H disease, which manifests as haemolytic anaemia; and (4) homozygous α-thalassaemia, in which the afflicted fetus dies at or around term from hydrops fetalis. These four syndromes are due to the deletion of from one to all four copies of the α-globin genes. In this study, we have characterised α-thalassaemia in people of African origin. Haemoglobin screening programmes have shown that α-thalassaemia occurs in the black population[8–10]. Recently we have demonstrated by complementary DNA–DNA hybridisation that in black individuals with clinically well defined α-thalassaemia trait, two of the four normal α-globin genes were deleted[11]. However, in this population, haemoglobin-H disease is rare and homozygous α-thalassaemia has never been found[12,13]. For this study we have used the restriction endonuclease mapping technique of Southern[14] to delineate the nature of the deletion of the α-globin genes.

The two α-globin structural gene loci are 3.7 kilobases apart[15,16]. The presence of these two loci could be deduced by digestion with the two restriction enzymes, *Eco*RI and *Hpa*I. When cellular DNA from a non-thalassaemic individual (genotype: $\alpha\alpha/\alpha\alpha$) was digested with *Eco*RI, the two α-globin loci were located in a single DNA fragment about 23 kilobases in length. In the DNA of a patient with haemoglobin-H disease who had only one α-globin gene remaining ($--/-\alpha$), the *Eco*RI fragment which contained the single α-globin locus became shortened to 19 kilobases. In the silent carrier state (α-thalassaemia-2), in which two α-globin loci resided on one chromosome and a single locus resided on the other ($-\alpha/\alpha\alpha$), both the 23-kilobase and the 19-kilobase bands were found. The phenotype of α-thalassaemia trait with two α-globin genes deleted could arise from two types of gene arrangement. The two genes could be deleted either *in cis* or *in trans*, giving rise to heterozygous state of α-thalassaemia-1 ($--/\alpha\alpha$) or the homozygous state of α-thalassaemia-2 ($-\alpha/-\alpha$), respectively. These two gene arrangements could be distinguished, as *Eco*RI digests would show a single 23-kilobase normal fragment in the former, and a single 19-kilobase fragment in the latter (Fig. 1).

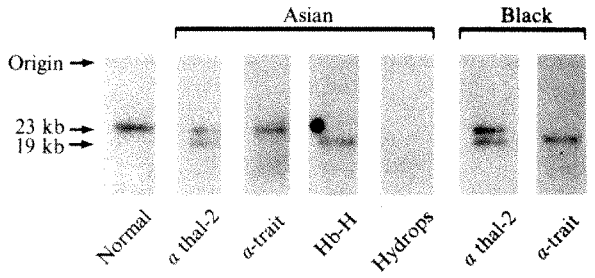

Fig. 1 *Eco*RI-digested human DNA hybridised with α-globin gene specific probe. Human DNA was extracted from white blood cells or placenta from normal individuals and patients with different α-thalassaemia syndromes using methods described previously[5]. DNA (10 μg) digested with *Eco*RI was separated by electrophoresis on 0.8% agarose gel and transferred on to nitrocellulose filters as described previously[17]. The filter was hybridised for 48 h in previously described conditions[17] with plasmid JW 101 (ref. 18) which contains the human α-globin complementary DNA insert and which has been nick translated and labelled with ^{32}P-dCTP and ^{32}P-dTTP according to the method of Maniatis *et al.*[19]. The filter was extensively washed and autoradiographed[17]. The numbers on the left indicate nucleotide pairs in kilobases (kb). The α-globin gene containing bands in Asians are shown on the left, whereas those of blacks are on the right. Note the difference in the patterns of α-thalassaemia trait (α-trait) in the two ethnic groups.

The arrangement of the α-globin genes could further be confirmed by digestion of the DNA with the enzyme *Hpa*I, which cleaves in between the two α-globin loci (Fig. 2). Normal DNA yielded two *Hpa*I fragments, 14.5 and 4.1 kilobases in length, which contained the 3′ and the 5′ α-globin loci, respectively[15,16]. In haemoglobin-H disease the single remaining locus contained in the 14.5-kilobase fragment was seen. In the silent carrier state both the 14.5-kilobase and the 4.1-kilobase fragments were present, the former containing two alleles, being

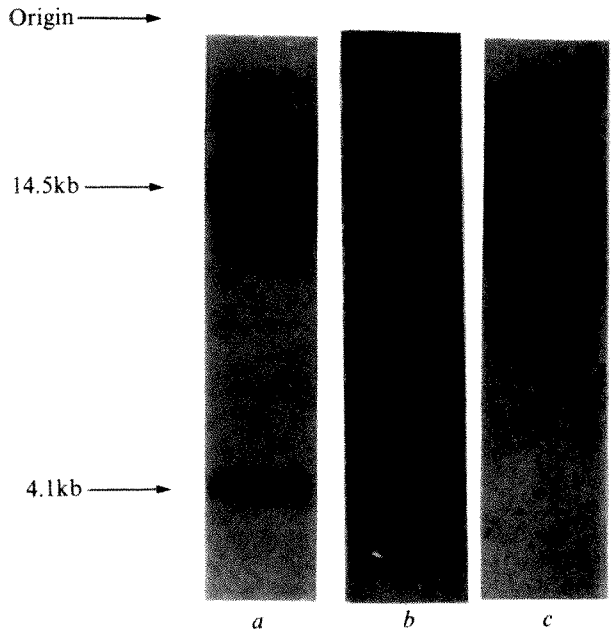

Fig. 2 *Hpa*I digested human DNA hybridised with α-globin gene-specific probe. The pattern seen in: *a*, normal ($\alpha\alpha/\alpha\alpha$) and α-thalassaemia-1 with deletion *in cis* ($--/\alpha\alpha$); *b*, α-thalassaemia-2 ($-\alpha/\alpha\alpha$); *c*, haemoglobin-H disease ($--/-\alpha$) or α-thalassaemia trait with deletion *in trans* ($-\alpha/-\alpha$).

more intense than the latter with one allele. Again, the two genotypes which produce the clinical state of α-thalassaemia trait could be distinguished from each other, as deletion *in cis* ($--/\alpha\alpha$) gave both the 14.5 and 4.1-kilobase bands, whereas deletion *in trans* ($-\alpha/-\alpha$) produced only the 14.5-kilobase band.

We selected 15 black individuals with clinical diagnosis of α-thalassaemia trait. Rigid criteria were used to establish the diagnosis. These were: in the adult, a mean corpuscular volume (MCV) of less than 76 fl, normal haemoglobin A_2 and F, absence of iron deficiency and decreased α/β globin synthesis ratio; in the newborn period, an MCV of less than 96 fl, haemoglobin Bart's of over 3% and persistence of microcytosis at the age of 6–12 months in the absence of iron deficiency. Table 1 summarises the pertinent haematological findings. Haemoglobin-H was not detectable in these patients and molecular hybridisation analysis showed that they had two copies of α-globin structural genes per diploid genome[11]. Restriction endonuclease mapping showed that all 15 had the 19-kilobase band on *Eco*RI digest, and only the 14.5-kilobase band on *Hpa*I digest. Thus, the two remaining α-globin genes are located on opposite chromosomes ($-\alpha/-\alpha$) (Fig. 1). We also studied 15 adult Asian patients with α-thalassaemia trait. This diagnosis was also made according to the criteria listed, and in addition, six of these patients were parents of hydropic fetuses. Molecular hybridisation confirmed

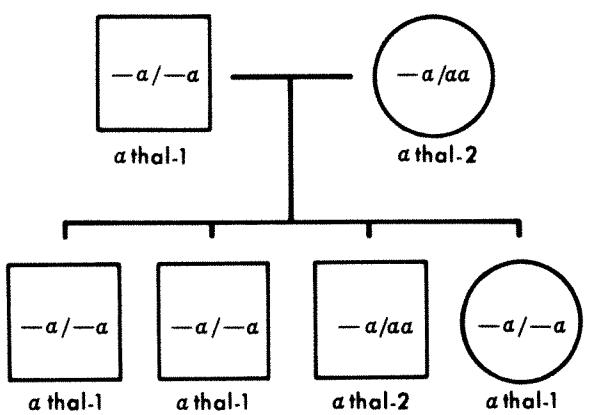

Fig. 3 Inheritance of α-thalassaemia in a black family. The mean corpuscular volume in femtolitres (normal > 80) in the family members are: I-1 : 70, I-2 : 81, II-2 : 68, II-3 : 78 (age 4 yr, normal > 75), III-4 : 62. The apparent direct transmission of α-thalassaemia trait is due to the presence of α-thalassaemia-2 in the haematologically normal mother.

that they had two α-globin genes per diploid genome[11]. Restriction analysis showed that they all had the normal 23-kilobase *Eco*RI band and both *Hpa*I bands, indicating that the deletion of the two genes had occurred on the one chromosome ($--/\alpha\alpha$).

We used these enzymes to map the α-globin genes in 211 black Americans. They were not selected for α-thalassaemia, none had haemoglobin-H disease, but some had the β-structural mutants S and C (Table 2); 70.6% had the normal α-globin genotype, 27.5% had two α-globin bands on *Eco*RI, characteristic of the silent carrier state, and 1.9% had the 19-kilobase *Eco*R1 band and only the 14.5-kilobase *Hpa*I band characteristic of the genotype of $-\alpha/-\alpha$. The frequency of the single α-globin locus ($-\alpha$) was calculated to be 0.16.

We also investigated the mechanism of transmission of α-thalassaemia. Previously, 'direct transmission' of α-thalassaemia trait from parent to offspring in the black has been taken as evidence for the presence of the α-thalassaemia-1 genotype ($--/\alpha\alpha$). When we studied with restriction enzyme analyses two families in which direct transmission seemed to have occurred, we found that the parent with α-thalassaemia trait had the genotype of homozygous α-thalassaemia-2 (that is, deletion of the two α-globin genes on opposite chromosomes), and the haematologically normal spouse had the 23- and 19-kilobase bands containing the α-globin genes characteristic of α-thalassaemia-2 carrier. The latter diagnosis was previously unrecognised without restriction endonuclease mapping. Figure 3 illustrates the findings in one such family. As the frequency of α-thalassaemia-2 is 27.5%, this type of inheritance will explain the so-called direct transmission in most cases.

These findings directly confirm the hypothesis first proposed by Lehmann on the genetic basis of α-thalassaemia and the lack of the severe form of α-thalassaemia in the black population[20]. Using the percentages of haemoglobin S in sickle-cell trait as an indicator of α-thalassaemia, Altay *et al.*[9] in the African population and Brittenham[21] in Asian Indians found a trimodal distribution of the percentage of haemoglobin S level, of about, 25, 33 and 45%. They concluded that the two lower percentages of S are due to the co-existence of α-thalassaemia trait and α-thalassaemia-2, respectively. The present study directly demonstrates the frequent occurrence of the α-thalassaemia-2 genotype. It seems that the presence of 1–2% haemoglobin Bart's in cord blood used as the criterion for diagnosis of α-thalassaemia-2 grossly underestimates the presence of the α-thalassamia-2 gene, as electrophoresis of cord blood showed that only a few per cent of the black population had increased haemoglobin Bart's, whereas restriction enzyme analysis demonstrated the prevalence of α-thalassaemia-2 carrier to be 27.5%. This finding agrees with that of Pierce *et al.*[10] who detected a high incidence of α-thalassaemia in black recruits by globin chain synthesis studies.

Table 2 α-globin genotype in black Americans

Genotype	No.	Percentage
$\alpha\alpha/\alpha\alpha$	149	70.6
$-\alpha/\alpha\alpha$	58	27.5
$-\alpha/-\alpha$	4	1.9
Total	211	100

Frequency of $(-\alpha)$ genotype = 0.16.

These results satisfactorily explain the distribution of the different clinical syndromes of α-thalassaemia in the black population. Whereas α-thalassaemia-1 with deletion of the two α-globin genes *in cis* $(--/\alpha\alpha)$ is common in the Asian, this genotype is rare in the black. The fatal form of α-thalassaemia associated with deletion of all the α-globin genes $(--/--)$ will therefore not be found. Haemoglobin H disease $(--/-\alpha)$ will also be rare as it requires the combination of an α-thalassaemia-1 gene with an α-thalassaemia-2 gene. On the other hand, in those parts of the world such as the West Indies, where there is a high incidence of mating between people of African and Asian origin, a high incidence of haemoglobin-H is found.

Phosphorylation in a simple system of lipids and chloroplast ATP synthetase driven by pulsed ionising radiation

WE report here the observation of an ADP-dependent phosphorylation reaction in an artificial lipid vesicle system driven by pulsed ionising radiation. This reaction is completely dependent on the only enzyme incorporated into the phospholipid vesicle bilayer, the ATP synthetase (CF_0–CF_1) complex from spinach chloroplasts. Previous attempts to demonstrate directly an obligatory coupling between the proton pumping and phosphorylation activities of an ATP synthetase enzyme in resolved, reconstituted vesicle systems have required the presence of additional protein components[1–3] to generate the transmembrane *p*H gradient and/or membrane potential postulated by the chemiosmotic hypothesis[4] as the driving force for the ATP synthesis reaction:

$$ADP + P_i + nH^+_{in} \rightleftharpoons ATP + H_2O + nH^+_{out}$$

Pulsed high-energy radiolysis of water produces, in a very brief time increment, significant quantities of protons along with the highly reactive transient species e^-_{aq}, $^{\cdot}OH$, and $^{\cdot}H$ ($\Delta[H^+] \sim 10^{-5}$ M in 50 ns)[5]. Assuming a uniform production of protons throughout the aqueous media, differential buffering between the inner and outer aqueous compartments of phospholipid vesicles will result in the effectively instantaneous formation of a transmembrane proton gradient. We have applied the pulse radiolysis technique to drive the ATP synthetase activity of phospholipid vesicles reconstituted with the chloroplast CF_0–CF_1 enzyme complex.

Single-walled bilayer vesicles were prepared in dilute buffer from purified soy phospholipids (asolectin) by either a sonication[6] or a detergent–dilution[7] technique. The CF_0–CF_1 ATP synthetase complex extracted from spinach was incorporated into the vesicles as previously described[8]. Immediately before irradiation, a highly buffered solution containing ADP and $^{32}P_i$ was added; then the sample was deoxygenated with nitrogen, sealed in a small glass vial and irradiated. Details of the specific reaction mixtures for each experiment and the method of assay for esterified $^{32}P_i$ are given in the footnotes to the tables. The radiation dose given per pulse was determined by a method previously described[9].

From Table 1 it is apparent that phosphorylation only occurred in irradiated samples, and that the yield of phosphorylated product reached a limiting value at high cumulative dose levels. This is consistent with the predicted radiation inactivation of the enzyme; based on studies with rat-liver mitochondria, inactivation would be expected in the 10^2 krad range[10]. Significantly, the amount of $^{32}P_i$ esterified exceeded, on a molar basis, the amount of enzyme added by a factor of about 8 in the cholate-dilution vesicles and by a factor of about 2 in sonicated vesicles. Even assuming that all of the enzyme added was active and properly

Table 1 Dose dependence for pulse radiolysis-driven phosphorylation in artificial lipid vesicles

No. of pulses*	Pulse frequency (Hz)	$^{32}P_i$ esterified (nmol ml^{-1})† Cholate-dilution vesicles‡	Sonicated vesicles§
0	—	0	0
100	120	0.33	
500	120		1.46
1,000	5	0.92	1.55
1;000	120	0.95	1.63
10,000	120	0.97	

*Radiation dose in each pulse, 1 krad. Pulse width, 50 ns.

†Residual radioactivity after extraction of unreacted ^{32}P-orthophosphate as phosphomolybdic acid as described[3,12] $^{32}P_i$ specific activity, 3,375 c.p.m. nmol^{-1}.

‡Cholate-dilution vesicles were prepared as follows: 20 mg purified soy phospholipid was disolved in 0.5 ml of a solution containing 0.2 M sucrose, 1.4% Na-cholate, 1 mM tricine (*p*H 8.0) and 3 mM $MgCl_2$. This was mixed with an equal volume of CF_0–CF_1 complex containing 8.0 mg protein per ml. After 20 min at 4 °C, 16-μl aliquots of the enzyme–lipid mixture were diluted into 0.8 ml volumes of a solution containing 0.8 mM tricine (*p*H 8.0), 3 mM $MgCl_2$, 12 mM glucose, 0.12 mM KNO_3. After 1–2 min, 0.1 ml 10% defatted bovine serum albumin and 0.1 ml of the external buffer solution (2 mM ADP, 20 mM $Na_2H^{32}PO_4$, 25 μg ml^{-1} hexokinase, 200 mM HEPES (*p*H 8.25)) were added, the sample (1 ml) was deoxygenated, sealed in a small glass vial (1 cm i.d.) and immediately irradiated.

§Sonicated vesicles were prepared by sonicating (in a bath type sonicator) 2.5 mg purified soy phospholipids in 1 ml of a solution containing 1 mM tricine (*p*H 8.0), 3 mM $MgCl_2$, 0.2 M sucrose. After the suspension cleared (~15 min), 0.1 ml of the CF_0–CF_1 complex (8.0 mg protein per ml) and 0.15 ml of a solution containing 200 mM glucose, 1 mM KNO_3 was added and the suspension sonicated an additional 3 min. To this reconstituted system, 0.15 ml 10% defatted bovine serum albumin and 0.15 ml of the external buffer solution were added and samples (0.5 ml) were deoxygenated, sealed and irradiated.

incorporated into the vesicles, this result indicates multiple turnover of the enzyme. Although the relative yield of phosphorylated product (per mg protein) was greater using cholate dilution vesicles, subsequent studies were performed with sonicated vesicles to permit greater variation in both phospholipid and enzyme concentrations.

The data from several preparations of sonicated vesicles are summarised in Table 2. A reasonably good correlation was observed between the yield of phosphorylated product and the absolute quantity of enzyme added. When the CF_0–CF_1 complex was irradiated in the absence of lipid vesicles, the formation of phosphorylated product was greatly diminished, although a slight incorporation of radioactive phosphate into an organic product (~0.3 nmol per mg protein) was observed. This residual phosphorylation may result from some phospholipid

Table 2 Effect of enzyme concentration on pulse radiolysis-driven phosphorylation

Enzyme (mg ml^{-1})	Lipid (mg ml^{-1})	$^{32}P_i$ esterified (nmol ml^{-1})	$^{32}P_i$ esterified per mg protein
0.47	2.6	3.20	6.80
0.53	1.7	1.46	2.75
1.24	2.6	3.51	2.80
1.60	13.3	5.25	3.28
1.71	26.7	4.48	2.62
1.87	26.6	6.61	3.53

Sonicated vesicles were prepared as described in Table 1, except the enzyme and lipid concentrations were varied to give the final concentrations indicated. Irradiation was with 500 pulses (50-ns pulsewidth) at 120 Hz. Dose per pulse = 1 krad.

Table 3 Substrate and enzyme requirements for pulse radiolysis-driven phosphorylation

Conditions*	$^{32}P_i$ esterified (nmol ml^{-1})
Control	4.48
Heat-denatured enzyme†	0.16
ADP omitted	0.36
Enzyme omitted	0.00
Sonicated in 'external buffer'‡	2.28

*Sonicated vesicles containing 26.7 mg ml^{-1} soy phospholipid and 1.71 mg ml^{-1} CF_0–CF_1 complex were prepared as described in Table 1. Each sample was irradiated with 500 pulses at 120 Hz (pulsewidth, 50 ns; dose per pulse, 1 krad).

†The enzyme was heated to 55 °C for 10 min immediately before incorporation into the vesicles.

‡Sonicated vesicles were prepared as described in Table 1, except that the external buffer was added with the enzyme before the 3 min sonication step.

contamination of the CF_0–CF_1 preparation[8], or may be related to the observation that acid denaturation of soluble CF_1, in the absence of membranes, can result in the formation of a small amount of ATP[11].

The data in Table 3 demonstrate that the radiolytically driven phosphorylation reaction required the CF_0–CF_1 ATP synthetase complex in active form. Furthermore, the esterification of $^{32}P_i$ occurred at significant levels only when ADP was added to the system. This strongly suggests that the initial product of the radiolytically driven reaction was in fact ATP. The interpretation is further strengthened by the finding that all of the $^{32}P_i$-labelled product is acid stable (100 °C, 10 min, 1 M HCl), as expected for glucose-6-phosphate. These results also eliminate the possibility of a radiolytically initiated ADP–$^{32}P_i$ exchange reaction. The trace amount of $^{32}P_i$-labelled product formed in the absence of added ADP may result from residual bound ADP added with the enzyme[13].

Considered within the context of the chemiosmotic hypothesis[4], the radiolytically driven phosphorylation reaction studied here appears to be reasonably efficient, although a definitive determination of the H^+/ATP ratio cannot be made without an accurate characterisation of the structure of the vesicles used in this system. Assuming a vesicle internal radius of 100 nm, for example, the number of radiolytically generated internal protons per ATP synthesised would be approximately 800.

Surprisingly, sonication of the vesicles in the presence of high external buffer did not completely eliminate the formation of ATP in this system (Table 3). Incomplete equilibration of the external and internal buffers could account for the residual phosphorylation activity, but this does not seem likely after sonication. Alternatively, it is probable that generation of protons in ~10^{-8} s produces a transient large *p*H drop, the relaxation of which is limited only by buffer protonation. The extent to which to the initial reaction of protons with the CF_0–CF_1 complex can compete with buffer protonation reactions in the short time scale involved here could determine, at least in part, the efficiency of the overall ATP synthetic reaction, with limited dependence on the internal buffer concentration. In any event, there is evidence to indicate that the effects of internal buffers on phosphorylation efficiency are complex[14].

Irradiation, in identical conditions (500 pulses, 120 Hz, 1 krad per pulse), of the solution which was used for the internal aqueous phase of the vesicle produced a long-term *p*H drop of ~1.2 units. Assuming a chemically inert lipid bilayer, this would allow a maximum steady state transmembrane gradient of ~1.2 *p*H units. A possible contribution by a radiolytically generated transmembrane electrical potential cannot be ruled out, although yields of ATP per mol of CF_1 comparable to those reported here have been measured in chloroplasts subjected to a similar small *p*H gradient by a dark *p*H jump (T. Graan and N. E. Good, personal communication).

The study of CF_0–CF_1-catalysed ATP formation by the pulsed irradiation technique (Fig. 1) provides an opportunity to resolve kinetically the mechanistic processes involved in the ATP synthetase and proton pumping activities of this enzyme. Further, the ability to generate a significant transmembrane pH gradient on a nanosecond time scale should contribute to the study of a wide range of membrane processes.

In vivo reduction of cyclopropene by *Azotobacter vinelandii* nitrogenase

NITROGENASE from N_2-fixing aerobes such as *Azotobacter vinelandii* is stable to air in crude extracts but on fractionation into its two protein components, Fe–Mo protein and Fe protein it manifests the O_2 sensitivity characteristic of other nitrogenases[1]. This difference between the air-stable and air-labile forms of the enzyme has been ascribed to various causes[2–4]. More generally, the incompletely defined correlations between *in vivo* and *in vitro* nitrogenase function with respect to optimal component ratio[5], local pH[6], ATP stoichiometry[7], reductant[8], catalytic behaviour[4,9] and other important enzymatic parameters are a source of ambiguity in biochemical studies on the cell-free enzyme. In principle, effects from changes in many of these parameters can be studied by parallel *in vivo* and *in vitro* substrate reduction and inhibition studies. In practice[10], restrictive limitations are imposed by the paucity of nitrogenase substrates that are at once (1) well bound, (2) capable of diagnostically complex chemical interactions, and (3) compatible with function of the enzyme in living microorganisms. For example, among known substrates other than N_2 itself, C_2H_2 is deficient in reduction complexity[10], HCN is excluded by its cytotoxicity and acrylonitrile, which displays interesting product patterns[11], is a poor substrate[12]. Recently, cyclopropene was shown to undergo ATP-dependent nitrogenase-catalysed reduction to propene and cyclopropane *in vitro*[13]. The product ratio of ~2:1 alkene : cycloalkane was found to be insensitive to purification over a specific activity range of 40–1,200 in conventional assay conditions. We report here results of further nitrogenase–cyclopropene investigations which establish that: (1) nitrogenase in living *A. vinelandii* catalyses cyclopropene reduction to the products observed *in vitro* in the same ~2:1 ratio; the K_m for formation of either product is very similar if not identical to that obtained with cell-free enzyme; (2) with purified components (specific activity up to 2,000) at optimal stoichiometry, the K_m for formation of the reduction products (propene and cyclopropane) is 0.01 atm, corresponding to a molar K_m as low as that of N_2 (and C_2H_2). These findings strengthen the case for catalytic similarity between *in vivo* and *in vitro* nitrogenase. Conversely, they substantiate the importance of cyclopropene product ratio as a chemical probe for the enzyme and as an important new criterion for nitrogenase biomimetic chemistry.

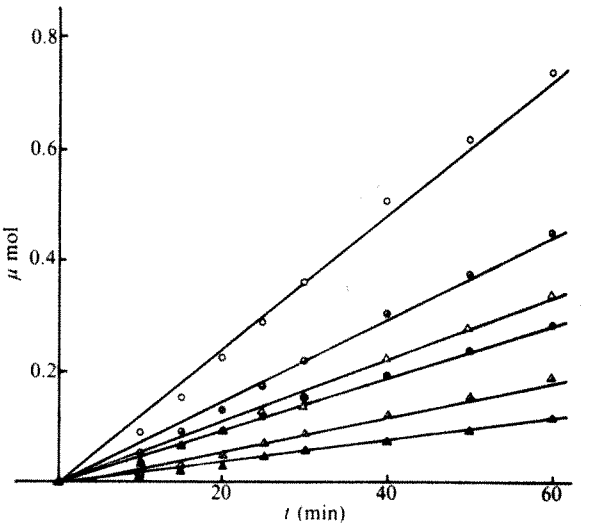

Fig. 1 CO inhibition of cyclopropene reduction by *A. vinelandii* cultured on N-free Burk's medium. The time course of formation of products was monitored by GC after addition of substrate (0.04 atm), inhibitor (as shown below), O_2 (0.1 atm) and 206 Klett-ml of log phase culture. $P_{CO} = 0.0026$ atm: propene, ●; cyclopropane, ▲. $P_{CO} = 0.0013$ atm: propene, ∅; cyclopropane, △. Control (no CO): prm, ○; cyclopropane, △.

Cyclopropene (0.05 atm in Ar or He) was incubated at 30 °C and shaken in septum-stoppered 21 ml vaccine bottles with 2 ml of log phase *A. vinelandii* OP culture grown on a modified[14] N-free or NH_3-supplemented Burk's medium. Cyclopropene was prepared purified and analysed as described elsewhere[13,15]. In aerobic assays, the gas phase also contained 1–5% O_2 (care was taken to avoid O_2 inhibition[16]). Respiration-dependent reduction to both propene (~2.1) and cyclopropane (~1.0) was observed with N_2-fixing cultures; the reduction ratio remained constant throughout the linear portion of product evolution time course experiments (Table 1). Cultures grown on the NH_3 medium were devoid of cyclopropene reduction activity (Table 1). Only respiring, N_2-fixing *Azotobacter* possess C_2H_2 reduction activity[4,9].

Table 1 Requirements for reduction of cyclopropene by *A. vinelandii*

Whole cell assay system	Medium	Propene activity (nm per Klett-ml min) × 10^3	Cyclopropane activity (nm per Klett-ml min) × 10^3	C_2H_4 activity (nm per Klett-ml min) × 10^3
Complete	N-free	61	30	152
Complete	$+NH_3$	<1	<1	<1
$-O_2$	N-free	<1	<1	<1

Table 2 Comparison of kinetic parameters and product ratios for *in vivo* and *in vitro* nitrogenase reduction of cyclopropene

Enzyme state	Propene formation		Cyclopropane formation				
	K_m(M)	V_{max}/V_{max} (C_2H_2)	K_m(M)	V_{max}/V_{max} (C_2H_2)	R*	C_2H_2 K_m(M)†	N_2 K_m(M)‡
In vivo	1.3×10^{-4}	0.38	1.4×10^{-4}	0.20	1.9	2.2×10^{-4}	—
In vitro	1.1×10^{-4}	0.29	1.0×10^{-4}	0.14	2.1	1.3×10^{-4}	1×10^{-4}

*Ratio V_{max} (propene)/V_{max} (cyclopropane). †This work. ‡Ref. 1.

Inhibition of the *in vivo* cyclopropene reduction by N_2 or CO was also consistent with identification of nitrogenase as the responsible catalyst. At a partial pressure of 0.91 atm, N_2 caused a reversible decrease in the cyclopropene reduction rate of 73% at P (cyclopropene) = 0.02 atm. CO was highly effective in inhibiting cyclopropene reduction *in vivo* (Fig. 1). CO has been previously shown to be a potent inhibitor of N_2 and C_2H_2 reduction by nitrogenase[1,4]. (The normal propene:cyclopropane ratio seemed slightly increased in the presence of CO.)

Lineweaver-Burk plots of propene and cyclopropane formation rate dependence *in vivo* on initial cyclopropene pressure were linear (Fig. 2*a*) and gave an average K_m value of 0.014 ± 0.002 atm for each product. In identical conditions, a K_m value of 0.006 atm was found for C_2H_2, in good agreement with most literature data[1,4]. Using a value for the Henry's law constant at 30 °C for cyclopropene of 4.6×10^6 mm (C.E. McKenna and M-C. McKenna, unpublished work) and a literature value of 1.1×10^6 mm for that of C_2H_2 (ref. 17), molar K_m values for the two substrates are found to be about the same (Table 2). Of other nitrogenase substrates, only N_2 has as low a K_m value[1,4]. The ratio V_{max} (cyclopropene)/V_{max} (C_2H_2) from these experiments had an average value of 0.58.

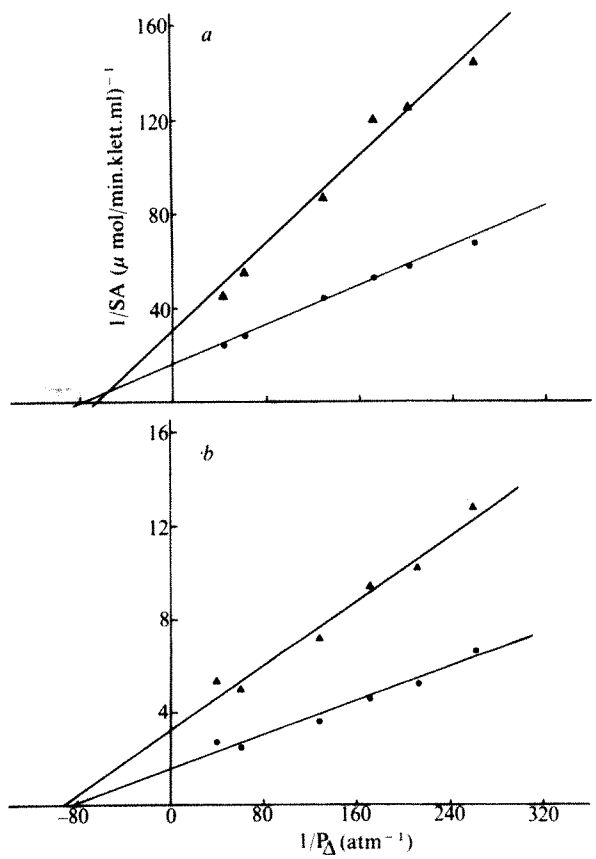

Fig. 2 *a* Double reciprocal (Lineweaver–Burk) plot of reduction rate dependence on cyclopropene pressure with *A. vinelandii* cultured on N-free Burk's medium. After addition of O_2 (0.1 atm) and 218 Klett-ml of log phase culture, time course plots for product formation (GC) were made at each substrate pressure and the initial rate (V) found from the linear portions; V values were divided by the product of the cell density (Klett units) and assay culture volume to obtain specific activities (SA values). The data were fitted to a linear regression curve as shown. Propene, ●; cyclopropane, ▲. *b*, Double reciprocal (Lineweaver–Burk) plot of reaction rate dependence on cyclopropene pressure with purified nitrogenase components from *A. vinelandii*. The component ratio was 1:2 Av1:Av2. Assay conditions were as described elsewhere[13]. Time course plots for product formation (GC) were made at each substrate pressure and the initial rates were found from the linear portion; V data were then converted to SA values (V per mg limiting protein-min). The data were fitted to a linear regression curve as shown. Propene, ●; cyclopropane, ▲.

Similar kinetic experiments were done using highly purified Av1 and Av2 recombined in a 1:2 ratio (Fig. 2*b*). Formation of both cyclopropene products was characterised by the same K_m value within the error of the measurement; the ratio V_{max} (cyclopropene)/V_{max} (C_2H_2) was about 0.43. Comparison of the *in vivo* and *in vitro* results (Fig. 2*a*,*b* and Table 2) reveals that the K_m values for both propene and cyclopropane formation are strikingly similar and that over a pressure range from 0.29 K_m to 1.8 K_m no variation in the propene:cyclopropane ratio is observed; the V_{max} (propene):V_{max} (cyclopropane) ratio is unchanged from the experimental ratio values.

Cyclopropene is thus comparable to N_2 and C_2H_2 in effectiveness as a nitrogenase substrate both *in vivo* and *in vitro*. As a catalyst for cyclopropene reduction, *Azotobacter* nitrogenase gives similar kinetics (K_m, V_{max}) whether in intact cells or assayed as an isolated enzyme in specified standard conditions. It is clear that its overall catalytic properties with the new substrate are not greatly affected by removal from the cell and purification; to the extent that a nitrogenase K_m value inversely reflects active site binding, this means that the relatively bulky cyclopropene molecule has equivalent access to the *in vivo* and *in vitro* enzymes.

The observations described here show the potential of cyclopropene product stoichiometry as a chemical probe for nitrogenase directly[10,15,18] and for chemical models of the enzyme[19,20].

The effectiveness of cyclopropene as an *in vivo* nitrogenase substrate also suggests investigation of the substitutional relationship between cyclopropene and C_2H_2 with other C_2H_2-inhibited reductases (such as hydrogenases[21]) in N_2-fixing bacteria.

Reduction of cyclopropene as criterion of active-site homology between nitrogenase and its Fe–Mo cofactor

THE nitrogenase Fe–Mo cofactor (FeMo-co)[1] is usually characterised by its unique ability to restore N_2-fixing ability to extracts of certain nitrogenase-less mutants[1,2] and by its spectral properties, some of which can be correlated with those of the FeMo protein itself[3]. The role of FeMo-co in nitrogenase function is not yet clear. Recently, it was reported that uncomplemented FeMo-co catalysed BH_4^- reduction of C_2H_2 to C_2H_4 in a CO-inhibited, non-ATP-dependent process[4]. This was taken as evidence that FeMo-co is the active site for N_2 reduction and binding in nitrogenase, although conversion of N_2 to NH_3 by cofactor-BH_4^- mixtures was not observed[4]. C_2H_2 is readily reduced by many homogeneous and heterogeneous catalysts and can give only a single 2 e^- reduction product, urging caution in exclusive reliance upon it as a model substrate[5,6]. The observation that nitrogenase catalyses reduction of cyclopropene to both propene and cyclopropane in a ~2 : 1 ratio *in vitro*[7] and also *in vivo*[8] suggests a more demanding criterion[8] for evaluation of FeMo-co catalysis, one which still avoids the difficult energetic requirements for N_2 activation and reduction. This new criterion is strengthened by the fact that cyclopropene competitively inhibits N_2 (ref. 9). We find that incubation of FeMo-co with a suitable 'apoprotein' extract yields a reconstituted FeMo-protein activity for reduction of cyclopropene to propene and cyclopropane. FeMo-co alone, however, only catalyses cyclopropane formation in the conditions described[4] for C_2H_2 reduction. This result and other considerations suggest that active site homology between FeMo-co and nitrogenase has not yet been fully demonstrated on a function basis.

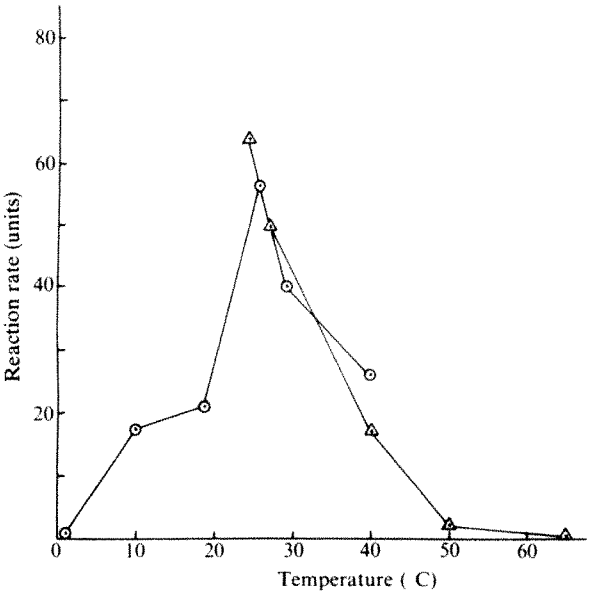

Fig. 1 Initial reaction rate–incubation temperature profile for FeMo-co-dependent BH_4^- reduction of C_2H_2 to C_2H_4. Identical 50 μl samples of FeMo-co were assayed as described in the text. ○, experiment 1; △, experiment 2.

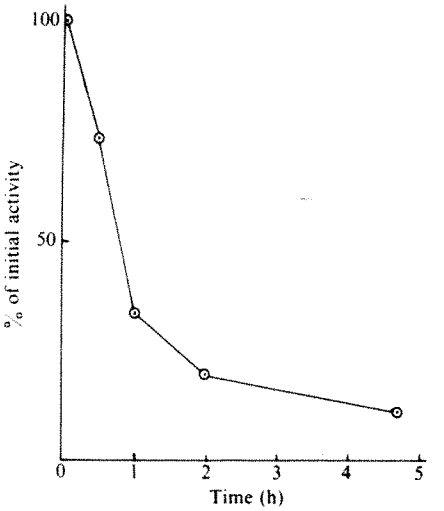

Fig. 2 Inactivation of the FeMo-co catalyst on exposure to air. 500 μl of the FeMo-co preparation was placed in an open 13 × 125 mm test tube and agitated at 150 r.p.m. in a 25 °C waterbath. At the indicated times 50 μl aliquots were removed and assayed for C_2H_2 reduction activity as described in the text.

FeMo-co was extracted from recrystallised *Azotobacter vinelandii* FeMo protein (Av1), specific activity 2,100[9], by a procedure adapted from that of Shah and Brill[1]. Typically, 140 mg Av1 in 2.8 ml of 25 mM Tris-HCl, *p*H 7.4 containing 250 mM NaCl was acidified by addition of 0.54 ml of 1 M citric acid at 4 °C. After 3 min, 2.4 ml of 0.5 M potassium phosphate, *p*H 9.0 was added dropwise with stirring and the protein precipitate was centrifuged for 7 min at 4,500 *g*. The pellet was extracted with 2.0 ml of dimethylformamide (DMF). The resulting suspension was clarified by centrifugation, and the pellet extracted with 2 ml of *N*-methylformamide (NMF). Both DMF and NMF were redistilled and contained 5 mM potassium phosphate (*p*H 8.0) and 2 mM dithionite. The NMF extract was layered on a 1 × 54 cm Sephadex G-100 column and developed in the same solvent (8 ml per h). FeMo-co elution from this column was monitored at 440 nm and was followed by 10-fold concentration under vacuum at 32 °C. All isolation and assay procedures were carried out under purified Ar. Samples were stored in liquid nitrogen and remained active for several weeks. BH_4^--dependent reductions were carried out in 22-ml serum vials containing (in 3 ml): 0.5 ml NMF; 80 mM sodium borate *p*H 9.6; 240 mM $NaBH_4$ and 4 mM sodium dithionite. Reaction was initiated with 50 or 100 μl FeMo-co concentrate and reduction of substrate (0.03–0.04 atm) was determined by GC. Activities (nmol substrate reduced per min) were corrected for background reduction, where necessary.

Shah and Brill[4] reported that C_2H_2 reduction by the BH_4^-–FeMo-co system at 25 °C was dependent on catalyst concentration but was not affected by C_2H_2 concentration (0.25–1.0 atm) nor by increasing the reaction temperature to 30 °C. No C_2H_6 was detected. Reduction activity was relatively stable to air inactivation (−16% after 18 h) at 4 °C.

Our results confirm that BH_4^--FeMo-co mixtures reduce C_2H_2 to C_2H_4 at an initial rate that depends on the FeMo-co concentration (determined over a range of 0 to 110 activity units). However, a dependence on the C_2H_2 concentration is observed at partial C_2H_2 pressures less than about 0.02 atm. Replacing the diluting gas (Ar) with He or H_2 (ref. 4) had no effect, and dithionite alone did not support reduction. Based on estimated Mo content, the specific C_2H_2 reduction activity of our FeMo-co preparations was 5–10% relative to homogeneous Av1 (Table 1), which compares well with the relative specific activity of 8% obtained by Shah and Brill[4]. The reaction rate increases above 0 °C to a maximum at 25–30 °C, then decreases (Fig. 1), presumably due to thermal lability of the catalytic species or to accelerated decomposition of the BH_4^-. The maximum in the

0028-0836/79/330611—02$01.00

© Macmillan Journals Ltd 1979

rate profile occurring over 25–30 °C (Fig. 1) would explain the apparent invariability of the reaction rate to temperature reported previously[4]. The $t_{1/2}$ for loss of C_2H_2 reduction activity in air-exposed FeMo-co at 25 °C was nearly 1 h (Fig. 2), while the $t_{1/2}$ for loss of reconstitutive activity was less than 1 min[1]. The C_2H_2 reduction activity was abolished by 0.12 atm CO or 1 mM KCN in the assay system. Besides C_2H_4, the major reduction product, we detected traces (up to 2%) of C_2H_6 (Fig. 3). A low level of background C_2H_2 reduction activity present in assay blanks did not account for this minor product (Fig. 3). Subsidiary formation of C_2H_6 is not observed in ATP-dependent reductions of C_2H_2 to C_2H_4 by either intact or reconstituted nitrogenase with dithionite as electron donor, but is typical of BH_4^- reductions catalysed by simple Mo-thiol complexes[5,6,10,11].

As shown in Table 1, cyclopropene is also reduced by the BH_4^--FeMo-co system, and at a rate ratio relative to C_2H_2 reduction that approximates the corresponding ratio in reconstituted (or intact) nitrogenase assayed in standard conditions. However, formation of both propene and cyclopropane was observed uniquely with intact or reconstituted FeMo protein, the cofactor alone yielding only cyclopropane. The 'apoprotein' extract from Kp 5058 used in the reconstitution experiments had no detectable catalytic activity before incubation with FeMo-co (Table 1). CO at 0.12 atm inhibited the FeMo-co cyclopropene reduction by 89%. A comparable inhibition is observed with nitrogenase at $\sim 10^{-3}$ atm but the comparison is complicated by the presence of both low and high affinity CO-binding sites[12].

It seems clear *a priori* that care must be exercised in drawing analogies between the catalytic behaviour of BH_4^-–FeMo-co[4] and nitrogenase. ATP dependence, the reductant and the assay *p*H are quite different for the two systems, while the known instability of FeMo-co in anaerobic aqueous solution[1] places in question the actual species responsible for substrate reductions by BH_4^-–FeMo-co mixtures. The striking differences in O_2-lability between the catalytic and reconstitutive FeMo-co activities may be relevant to this ambiguity, although the possibility that catalytic and complementive functions in native cofactor involve distinct and non-interactive moieties cannot be excluded. Our experiments verify that on the basis of Mo content, FeMo-co added to aqueous BH_4^- is a highly effective, CO-sensitive catalyst for C_2H_2 reduction[4]. C_2H_2 has been recognised as a potentially misleading model substrate for nitrogenase, especially when used alone[5,6,9,13]. By the more stringent cyclopropene criterion, BH_4^-–FeMo-co is not functionally equivalent to nitrogenase. Interestingly, the inability of the cofactor to reduce cyclopropene to propene is shared by a number of transition metal complexes that also catalyse C_2H_2 reduction, including a Mo-thiol system[14]. Incubation of FeMo-co with Kp 5058 'apoprotein' extract restored propene formation. To the extent that appropriate chemical equivalence exists among (1) the FeMo-co catalyst in aqueous, alkaline BH_4^-; (2) the spectroscopically defined FeMo-co species isolated in NMF; and (3) those Mo and Fe ions in intact nitrogenase assigned to the NMF cofactor, our findings are consistent with, but do not prove, the postulate that FeMo-co may represent only a portion of the active site responsible for binding and reducing N_2.

Table 1 Comparison of nitrogenase and FeMo-co as catalysts for C_2H_2 and cyclopropene reduction

Catalyst	Relative activity (C_2H_2)	Reduction rate ratio (cyclopropene/ C_2H_2)‡	Formation rate ratio (propene/ cyclopropane)
Intact nitrogenase*	1.0†	0.58	2§
Reconstituted nitrogenase*‖	—	0.56	2.5§
FeMo-co¶	0.05–0.10 #	0.40	<0.003
'Apoprotein' extract**	<0.0001	—	—

All data represent average values from two or more experiments.
* Assayed as described in ref. 7.
† Reference activity of Av1 (text) determined with 0.04 atm C_2H_2 and optimal amount of Fe protein.
‡ Equivalent pressures (0.03–0.04 atm) of both substrates. Initial rates derived from time course data were used.
§ Compare with refs. 7, 8.
‖ FeMo reconstitution was performed according to ref. 1 using 5 or 200 μl FeMo-co (text) and crude extract from Kp 5058. Some variability in activity was encountered at the reconstitution step.
¶ Assayed (text) using 50 or 100 μl of stock preparation.
Ref. 4 gives a value of 0.08.
** Taken in an amount sufficient to give optimal C_2H_2 reduction activity with 500 μl FeMo-co preparation and tested under standard nitrogenase[7] assay conditions.

We thank Dr B. E. Smith for a gift of Kp 5058 extract and for details of and help with the preparation of FeMo-co. This research was supported by grants from the Petroleum Research Fund of the American Chemical Society, the H. F. Frasch Foundation and the US Department of Agriculture.

matters arising

Evolution of dominance

CHARLESWORTH[1] has noted that very harmful mutant alleles in *Drosophila* are usually almost recessive in fitness to wild type, whereas in the case of mutants which are mildly disadvantageous, dominance of the wild type is much less marked. He points out that this result agrees well with Wright's theory of dominance but argues that it does not agree with Fisher's theory, for the following reason. In the case of dominance brought about by modifiers, the rate of change in frequency of a modifier is essentially independent of the fitness of the mutant homozygote, over most of the time that dominance is evolving. Thus, given equal times for evolution of dominance, dominance should be about as marked for mildly as for seriously disadvantageous mutants, which is not in fact the case.

However, the assumption of equal times may not be justified. A mutation which is lethal or near-lethal in laboratory conditions is likely to be very harmful in almost any environment and over very long periods of time, giving ample opportunity for the evolution of dominance. A mildly disadvantageous mutation, such as a change leading to an enzyme with a slightly altered *p*H or temperature optimum, is less likely to be disadvantageous in all conditions or for very lengthy periods of time. Thus, on Fisher's theory we should expect evolution of dominance to be much more marked in the case of very harmful mutants. The same would be true for evolution of dominance as envisaged by Haldane. Thus, the observed differences in degree of dominance do not provide a critical test of the relative merits of the three theories.

CHARLESWORTH REPLIES—The suggestion of Gale and Mackay is an interesting one, and introduces a new dimension to the theory of dominance modification. It is not obvious, however, that it invalidates my argument[1]. In the first place, there is no direct evidence for their view that mutations of large effect have lower environmental variance in their selection coefficients than mutations of small effect.

Nonetheless, even if we accept this idea, it is still not necessarily true that the conclusions of Gale and Mackay are correct. To evaluate them, we need to consider models of the modification of dominance at a locus subject to temporal fluctuations in selection coefficients. Theoretical studies[2–4] have shown that such fluctuations generate a probability distribution of gene frequency, even in an infinite population. The intensity of selection on a modifier of dominance in a given generation can be calculated by multiplying the advantage to the heterozygote by the frequency of heterozygotes[1]. The net intensity when gene frequencies and selection coefficients are fluctuating is given by the appropriate expectation over the joint distribution of gene frequency and selection coefficients. If the fluctuations in selective values are long term, the population will spend a long time in each environmental state, and so will be close to equilibrium for much of the time. When the population is in environmental state i, the intensity of selection on a modifier of effect Δh on the level of dominance of a mutant allele is thus approximated by $2u(\Delta h/h_i)$, where u is the mutation rate and h_i is the dominance coefficient in environmental state i (see ref. 1). There is thus no dependence on the strength of selection against the mutant homozygote, or on the amount of environmental change.

In the case of rapid environmental fluctuations, we need to use the gene frequency distribution at the locus subject to dominance modification[2–4]. A complete analytical solution for this is not yet available. To reconcile the experimental findings[1] with Fisher's theory we would have to find that the net intensity of selection for dominance modification is much weaker for genes of small average homozygous effect than for genes of large effect, or for genes whose selective values are constant in time. Genes of slight average homozygous disadvantage will tend to have a gene frequency distribution with a relatively high mean[3], so that the expected frequency of heterozygotes will be higher than for genes with a large effect. This will tend to counteract the smaller advantage of dominance modification in the heterozygotes, just as in the case with no fluctuations. A strong relationship between average homozygous effect, the intensity of environmental fluctuations and the advantage of dominance modification thus seems highly unlikely. A relationship of this sort may perhaps hold, but the effect might even work in the opposite direction. A definite answer to this question can only be obtained by carrying out the relevant calculations.

Haemoglobin S and *P. falciparum* malaria

PASVOL, WEATHERALL AND WILSON[1] have proposed an hypothesis to account for the protection given by haemoglobin S (HB S) against *Plasmodium falciparum* in heterozygotes for the sickle cell gene. This hypothesis depends on the argument that the last stages of a 48-h synchronous intra-erythrocytic growth cycle do not take place in the peripheral circulation, but in the deep capillary bed of some internal organ with a low oxygen tension, and that the low oxygen tension depresses invasion and development by the parasite in red cells containing HB S.

They therefore compared the rate of invasion and subsequent growth and development *in vitro* by parasites in conditions of low and high oxygen tension in red cells containing Hbs AA, AS and SS. The data given in their Table 1 do not, in our view, support the hypothesis that low oxygen tension impedes the rate of invasion and development by merozoites of *P. falciparum* in erythrocytes containing Hb S. We feel that the use of a ratio of the number of ring-form parasites per 100 red cells under low oxygen tension to that in aerobic conditions is misleading and statistically dubious, as a normal distribution could not be expected. However, one arrives at a conclusion very similar to that of the authors if one calculates the arithmetic differences for each of the pairs of measurements.

On the other hand, examination of the mean values, rather than the differences, for invasion and development in the various conditions, leads to a rather startling conclusion (our Table 1). With the exception of SS haemoglobin in aerobic conditions, all the other means are

0028-0836/79/330613—02$01.00
© Macmillan Journals Ltd 1979

virtually indistinguishable. However, Hb SS in aerobic conditions shows marked enhancement of invasion and development rather than, as suggested by the authors, suppression of growth in conditions of low oxygen tension. One accepts, of course, the statistical limitations of the relatively few experimental results for Hb SS.

Pasvol *et al.* also maintain that their hypothesis is supported by the data in their Tables 3 and 4. This interpretation ignores the significance of the large number of abnormal forms observed for red cells maintained in conditions of low oxygen tension (Table 3—74% for Hb AS; 20% for Hb SS—and Table 4). Furthermore, the use of a growth score from 1 to 6 for the different stages of parasite development, with abnormal forms being given an arbitrary value of 0, seems unjustifiable in the likely event that these abnormal forms represent the growth of the parasite to a stage at which no further development was possible, thus aborting the parasite life cycle and producing degenerate forms.

Table 1 Mean and s.e. for the number of ring-forms per 100 red cells after 12 h in aerobic or low oxygen conditions (data from Pasvol *et al.*[1])

	Aerobic	Low oxygen	
Haemoglobin			
AA	11.71±1.48	12.32±1.23	(13)
AS	11.52±1.31	10.35±1.34	(11)
SS	18.13±2.48	11.73±1.01	(4)

We have recently suggested that production of fatty acids by *Plasmodium knowlesi* and *Plasmodium berghei* may represent the molecular mechanism by which the plasmodial parasite damages red cells and produces haemolysis which may often be out of all proportion to the parasitaemia[2,3]. Similar evidence for the involvement of fatty acids in *Plasmodium lophurae* infections has been reported[4], and the whole question has been reviewed by Holz[5]. The fatty acids within the red cell are buffered by the haemoglobin that is present at high concentration, and Hbs AS, SS and SC are more effective than Hb AA at buffering fatty acids. This increase in buffering capacity has been rationalised at the molecular level in terms of the change in the amino acid residue at the 6β position[3,6], and could represent one of the mechanisms by which Hb protects against *P. falciparum* malaria.

In conclusion, we suggest that the data presented by Pasvol *et al.*[1] do not support their hypothesis concerning the mechanism for protection against *P. falciparum* malaria by sickle cell haemoglobin.

6. Laser, H. & Klein, R. A. *Biochem. Soc. Trans.* **5**, 292–293 (1977).

PASVOL, WEATHERALL AND WILSON REPLY—Laser and Klein might have been less startled by the results of their analysis of our data[1] if they had considered more carefully the haematology of sickle cell anaemia; taken into account our previous work which shows that *Plasmodium falciparum* preferentially invades young, metabolically active red cells[2,3]; and realised that the data in Table 1 of our paper deal only with parasite invasion and say nothing about development. The red cells in sickle cell anaemia have a short survival time which is reflected by a marked reticulocytosis[4]. Therefore, it is only to be expected that the degree of invasion of sickle cell anaemia (SS) cells by *P. falciparum* would be considerably greater than that of sickle cell trait (AS) or normal (AA) cells. For this reason the only valid comparisons are between cells of like ages (SS with SS, AA with AA) maintained aerobically or under reduced oxygen tensions. The data in Table 1 simply show that cells containing a significant amount of Hb S, such as SS, are invaded less actively under reduced oxygen tensions. However, we are grateful to Laser and Klein for restating that young red cell populations are preferentially invaded by *P. falciparum*.

The main emphasis of our paper was on parasite development once inside the red cells (Tables 3 and 4)[1]. There is no doubt that parasites in cells containing Hb S failed to develop, but only in conditions of reduced oxygen tensions. Furthermore, sickling was not required for this to occur. Laser and Klein are quite incorrect in their assumption that the abnormal forms of the parasite maintained in low oxygen conditions represent the growth of the parasite to a stage at which no further development was possible. Rather, they represent degenerate parasites at early stages of development. This was determined both morphologically and by analysis of pigment content. Furthermore, smears prepared at an early stage in the cultures showed that these abnormal forms were already present. Even if these were entrapped mature forms, which they were not, it is difficult to understand the marked differences observed between the aerobic and low oxygen tension cultures. The growth scores used were simply a means of condensing the data for a large number of experiments. Because the abnormal forms were mainly rings which had failed to develop, it seemed logical to rate them at less than the score of 1 designated to rings. Indeed, the results of the typical experiments in Tables 3 and 4 (ref. 1) stand without the need for growth score analysis.

Laser and Klein's hypothesis that Hb S has a greater buffering capacity than Hb A, thereby reducing fatty acid-induced haemolysis and impeding merozoite release from red cells[5] is interesting. However, at the stage of development before merozoites are released, over 75% of the haemoglobin has been digested by the parasite[6]. Indeed, on this basis it could be argued that relatively increased sensitivity of Hb A-containing cells to lysis might result in premature death and hence offer relative protection to normal individuals with malaria! Furthermore, Laser and Klein's hypothesis is quite incompatible with the mass of epidemiological data suggesting that protection of sickle cell heterozygotes is primarily against *P. falciparum* and not against all species of malarial parasites[7]. Our hypothesis takes into account the behaviour of the mature forms of *P. falciparum* which lodge in deep tissues where the oxygen tissues are low[8] and similar to those used in our experiments[9]. The tendency of Hb S to sickle under reduced oxygen tensions seems more rational than a subtle buffering effect of Hb S as yet not clearly defined in *P. falciparum* infections.

Thus, we believe that our findings, taken together with the essentially similar results of Friedman, who used an entirely different culture system[10], indicate that the growth of *P. falciparum* is limited in cells containing HB S exposed to reduced oxygen tensions and hence provide a reasonable explanation for the protective effect of Hb S against *P. falciparum* malaria.

STABLE ISOTOPES
Applications in Pharmacology, Toxicology and Clinical Research

Edited by T. A. Baille

Proceedings of a British Pharmacological Society Symposium held in January 1977
A group of internationally eminent contributors have produced here the first account of the very diverse applications of stable isotopes in the biomedical sciences.

The emphasis throughout is on the enormous scope in modern biological and medical research for the use of compounds labelled with the stable isotope of hydrogen, carbon, oxygen and nitrogen. Attention is given to the use of stable isotopes as tracers in metabolic studies, and the relative merits of this approach as compared with radiotracers is discussed. Novel aspects of labelling with stable isotopes are also dealt with, including the use of in vivo labelling of co-enzymes.

Other contributions concentrate on widely employed techniques, such as the use of stable isotope-labelled internal standards for quantitative analysis, by gas-chromatography-mass spectrometry, of drugs and their metabolites in body fluids.

MACMILLAN PRESS

CALL FOR PAPERS

To be published monthly from January 1980

Carcinogenesis

Aims and scope

Carcinogenesis has been designed as a multi-disciplinary journal bringing together all the varied aspects of research which would ultimately lead to the prevention of cancer in man. The journal will publish full papers and short communications which warrant prompt publication in the areas of carcinogenesis, mutagenesis; factors modifying these processes such as DNA repair, genetics and nutrition; metabolism of carcinogens; the mechanism of action of carcinogens and promoting agents; epidemiological studies; and the formation, detection, identification, and quantification of environmental carcinogens. Accepted manuscripts will be typeset, with high quality reproduction of photographs and illustrations, and the time from acceptance to publication will be no longer than 4 months and often less.

Instructions to Authors

Submission of Manuscripts

Detailed instructions are available from the publisher or either of the Executive Editors —

Synopses of the British Fauna, No. 15

British Coastal Shrimps and Prawns

Keys and Notes for the Identification of the Species

G. Smaldon

July 1979, vi + 126pp., £4.50/$9.50 0.12.659260.6

British Coastal Shrimps and Prawns is a delightfully illustrated synopsis, which should be of wide interest. Searching for these well-known animals is a popular summer occupation for many and a livelihood for a few, as the larger ones are of culinary importance. There are over 40 different species to be found around British shores. With this synopsis it will now be possible to identify them accurately, thanks to the general accounts of the biology of each species aided by the illustrations, which carefully portray characters of systematic importance without taking away any of the fascination of these lively crustaceans.

Like previous synopsis, this one is designed to be a working field and laboratory guide for professional and amateur biologists. It bridges the gap between popular field-guides and rare taxonomic treatises and monographs. This book will be of considerable value to fish and wild life biologists, natural historians, conservationists, oceanographers and marine scientists.

Cobalt in Biology and Biochemistry

R. S. Young

August/September 1979, x + 148pp., £11.80/$25.00 0.12.772750.7

Cobalt is in a unique position amongst the rarer heavy metals found in biological systems. It plays an essential role in ruminant nutrition, functions as a key element in Vitamin B_{12} and there is extensive evidence on the beneficial effects of small quantities of this metal on growth and development in many plants, animals and micro-organisms. With over forty years of experience of all aspects of cobalt, Dr. Young is eminently placed to make a critical assessment of such published investigations. This book takes the form of a review of the literature of cobalt and a reference manual that will enable researchers to benefit from an insight into the techniques employed and data obtained by others working in different areas of science. The cobalt content of fertilizers, waters and plants, cobalt in human and animal nutrition and the effects of cobalt on enzymes and micro-organisms are the subjects of just some of the chapters. The text is well documented with over a thousand references, allowing the agricultural, medical, biological and chemical researcher or student ample scope to pursue his own particular interest and to aquire ideas from other areas of science which may be applicable to his own.

The Design and Analysis of Longitudinal Studies

Their Role in the Measurement of Change

Harvey Goldstein

August/September 1979, xvi + 200pp., £11.80/$25.00 0.12.289580.0

The principal aim of this book is to set out the theoretical and practical problems of longitudinal studies within the general framework of studies concerned with understanding the process of change, in particular with developmental studies of children. The seven chapters are designed to lead the reader through the various stages of study design and analysis. They bring together in a systematic manner a widely scattered literature and assemble it in a coherent form. The topics dealt with include the practical problems of planning a study, the problems of sampling, the choice of suitable instruments to measure change, the development of statistical models for analysing change, the setting up of norms or standards over time and the design of computer programmes for processing longitudinal data. This will make stimulating and enlightening reading for students and research workers concerned with longitudinal studies of human populations as well as experimental studies, for example, of animals and plants involving longitudinal data.

Applied Problems in Memory

edited by M. M. Gruneberg and P. E. Morris

August/September 1979, xiv + 290pp., £12.40/$26.50 0.12.305150.9

Memory plays a vital part in all human activities and a proper understanding of how it works in real life is of great importance to many practical and social problems. However, for many years there has been less emphasis on research into applied problems of memory than into theoretical aspects. The present book examines applications of memory research with contributions from eminent workers in a number of areas. The book covers an impressive range of problems in which psychologists have recently been engaged, from the more obvious improvements in techniques for better remembering and in education, to less evident areas such as reading, memory in the aged, effects of stress, memory for skills and disorders of memory. The wealth of practical examples given throughout the text contribute to make a highly readable account of the subject. Within its wide scope, the book has a great deal to offer, not only to cognitive psychologists and workers in educational, clinical and industrial psychology, and in ergonomics, but also to anyone concerned with practical problems of memory at all levels.

Bacteria and Mineral Cycling

T. M. Fenchel and T. H. Blackburn

August/September 1979, xii + 266pp., £14.60/$31.00 0.12.252750.X

This book describes the influences of bacterial metabolism on the chemical environment of the biosphere. Its readers will include general microbiologists who want to find out about the ecological significance of micro-organisms; ecologists whose microbiological background is limited yet who wish to understand the role of bacteria in natural ecosystems; postgraducates in microbial ecology; and, finally, applied scientists — such as soil scientists or environmental engineers — involved with microbial ecosystems. The discussion of the energetics of bacterial processes serves as a general structure for most of the topics in the book since such considerations may afford insight into which processes are important in natural ecosystems. Within this basic framework, two major aspects of bacterial metabolism are stressed. Firstly, the chemical evolution of the biosphere and secondly, the manner in which different element cycles interconnect in natural ecosystems. Appendices are included with information that will enable those with only elementary knowledge of microbiology, energetics and ecology to understand the book with no trouble.

The Mathematics of Finite Elements and Applications III, MAFELAP 1978

edited by J. R. Whiteman

July/August 1979, c 520pp., £15.00/$31.50 0.12.747253.3

This volume records the Proceedings of the Third Conference on the Mathematics of Finite Elements and Applications, which was held at Brunel University in 1978. The decision to hold the conference followed the success of the previous two. The book contains the 10 main invited papers and 30 contributed papers, which were presented as lectures at the meeting, together with the abstracts of some 30 other papers that were presented in poster sessions. As before, the aim of the conference was to bridge the gap between the mathematical theory of finite elements and their applications. In particular, the main invited lecturers and the contributed papers were chosen so as to give coverage to as many as possible of the developments that have taken place in the finite element field in the three years since the last conference. Several chapters contain suggestions by the authors as to possible future paths that finite element techniques may take.

Frontiers of Speech Communication Research

edited by B. Lindblom and S. Öhman

August 1979, xxvi + 394pp., £18.80/$39.50 0.12.449850.7

The variety of new theories and related research is mirrored by the range of topics covered in this book: the quantitive modelling of the human vocal tract and its acoustical properties; acoustic phonetic description of various languages; the perception of speech and the development of objective measures of speech quality; applications of speech research; and the development of distinctive feature frameworks for linguistic theory. These original research reports, together with a number of review articles, provide a broad, up-to-date survey that makes the book a valuable reference work. The scope of the contributions will attract students and professionals engaged in research into speech communication, and those involved in the related fields of speech pathology, psychology, physiology and acoustics, and relevant areas of computer science and engineering.

Cognition and Perception Series

Decision Processes in Visual Perception

D. Vickers

August/September 1979, viii + 406pp., £21.60/$45.50 0.12.721550.6

The principal aim of this book is to present a theory of some of the fundamental mechanisms involved in the quantitative processing of visual information by human beings. In developing the theory, the book provides a detailed, constructive review of the various experiments and alternative hypotheses in each field of research. Throughout, the author relates his theory to other approaches, and presents it as the outcome of a logical sequence of alternative hypotheses. The various theoretical notions are dealt with in a concrete, intuitive way rather than a purely mathematical one, but abundant references are given to enable the reader to evaluate the argument in a more rigorous manner. The book will have a wide appeal to advanced undergraduates and researchers in experimental and cognitive psychology, particularly in the areas of perception, psychophysics and human information processing.

Drug Carriers in Biology and Medicine

edited by G. Gregoriadis

August/September 1979, c 300pp., £21.80/$46.00 0.12.301050.0

In theory, target selectivity for drugs can be achieved either on the basis of differential sensitivity or differential accessibility. However, it has only been in the last few years that the latter method has been considered practicable, by taking advantage of structures on the cell surface to bring about selective concentration of drugs by means of appropriate carriers. This is the first book to bring together work on a variety of drug carriers, and its publication now is evidence of the large amount of work already done and the success that has been achieved. The contributors survey the various approaches to the problem that have attempted using different types of carrier, and speculate on the possibilities of future research. The carriers dealt with include macromolecules and cells with homing properties harvested from biological systems, and synthetic carriers such as liposomes tailored to fulfil particular needs.

Electronic Imaging

edited by T. P. McLean and P. Schagen

August 1979, xviii + 522pp., £29.00/$61.00 0.12.485050.2

This book consists of the papers presented at an International Symposium sponsored and organised by the Rank Prize Funds, and held at the Royal Society, in September 1979. The aim of this symposium was to bring together experts on all aspects of electronic imaging, to exchange ideas and to benefit from their differing approaches to problems in this field. All the papers were given by invitation, which provided the opportunity for a balanced coverage of the many aspects of the subject: the pick-up display and recording of images of visible scenes, the processing of such images by electronic means, the sensing and use of images originating from non-visible radiation, such as infrared, microwave or ultrasonic and the interpretation by the eye-brain complex of the images presented to it.

Announcing Two New Journals from Academic Press

CRETACEOUS RESEARCH

Editor: R. A. Rayment, Paleontologiska Institutionen, Uppsala, Sweden

Editorial Board:

Peter Bengston (Sweden). Pierre-Yves Berthou (France). Tove Birkeland (Denmark). John Michael Hancock (UK). Erle G. Kauffman (USA). William James Kennedy (UK). Tatsuro Matsumoto (Japan). Dmitrij Pavlovich Naidin (USSR). Viera Scheibnerova (Australia). Seymour O. Schlanger (USA). Jorn Thiede (Norway). Hans R. Thierstein (USA).

Publication: Quarterly
Volume 1, Number 1 scheduled for March 1980

Subscription: Volume 1, 1980 £30.00 (UK only)
Overseas price to be announced

The Cretaceous system is of interest in many different disciplines, including palaeontology, stratigraphy, geophysics, oceanography, petroleum geology, geochemistry, sedimentology and tectonics. This new and wide-ranging journal aims to cover all these fields in their applications to Cretaceous research. It will also consider methodological papers if they can be applied to problems of interest to workers on Cretaceous rocks, and will give an important place to regional geology. Articles both long and short will be accepted but priority of publication will be given to short reports of research papers, in order to reduce publication delays to a minimum. All papers will be refereed, and may be submitted in English or French — papers in French must have a detailed summary in English. There will be scope for book reviews and the proceedings of symposia on subjects of relevance to the Journal's readers. *Cretaceous Research* will aim at high-quality contributions from the outset, and will be of great interest and value to all petroleum companies, libraries and individual workers on the Cretaceous or in foraminifera, plate tectonics, deep-sea research, regional geology or stratigraphy.

APPETITE

The Journal for Research on Intake, its Control and its Consequences

Chief Editors:

David Booth
Department of Psychology, University of Birmingham, P.O. Box 363, Birmingham B15 2TT, England.

Gordon J. Mogenson
Department of Physiology, Health Sciences Center, University of Western Ontario, London, Canada, N6A 5C1.

Judith Rodin
Department of Psychology, Yale University, Box 11A Yale Station, New Haven, CT 06510, USA.

Editorial Board 1979-1980:

G. A. Bray (USA). A. N. Epstein (USA). S. Garattini (Italy). A. E Harper (USA). D. J. McFarland (UK). P. R. McHugh (USA). E. Montgomery (USA). S. Nicolaïdis (France). D. Novin (USA). R. M. Pangborn (USA). E. T. Rolls (UK). P. Rozin (USA). F. J. Simoons (USA). U. Ungerstedt (Sweden). G. T. Wilson (USA).

An Advisory Board is to be announced.

Publication: Quarterly
Volume 1, Number 1 scheduled for March 1980

Subscription: Volume 1, 1980 £27.50 (UK only)
Overseas price to be announced

This new interdisciplinary journal concerns appetite — the tendency to seek and consume substances, be they food, water or any other ingestable materials — in all its aspects. It will cover the basic appetitive and ingestatory mechanisms of interest, including neural, systematic physiological, biochemical, pharmacological, sensory, psychological, social, cultural and economic processes. The applied study of appetite may be *clinical* (weight control, obesity, dietary health risks, anorexia nervosa and malnutrition), *industrial* (sensory evaluation, consumer research on foods and drinks and feed regulation for animal production) or *zoological* (conservation and pest control). Papers are invited from any of these areas, although material submitted should have substantial relevance to intake or attitudes to ingestable substances. An important aim of the journal will be to publish innovatory papers crossing the traditional boundaries between disciplines: reviews, comments and mini reviews with an integrative bias are welcomed as well as reports of new investigations. There will be a place for book reviews, abstracts or reports, summaries of papers published elsewhere, bibliographies and announcements of relevant meetings — indeed anything appropriate to the general area of appetite. This major new publication, while not affiliated to any society, is intended for researchers in a wide range of disciplines including psychology, anthropology, zoology, pharmacology, psychiatry, medical research, nutrition, food science and applied social science.

reviews

Prediction of a global cooling

William W. Kellogg

Ice or Fire? Surviving Climatic Change. By D. S. Halacy, Jr. Pp. 212. (Harper and Row: New York and London, 1979.) $9.95; £5.95.

THE fascinating subject of climate, and the likelihood that the world may soon witness another climatic change, has attracted the attention of several semi-popular book writers in the past few years (*Hothouse Earth,* by Howard Wilcox; *The Weather Machine,* by Nigel Calder; *The Genesis Strategy,* by Stephen H. Schneider; and *Climates of Hunger,* by Reid A. Bryson and T.S. Murray, to mention but four of the more celebrated ones). As one contemplates these very different approaches to climatic change and its many implications for mankind one is struck by the difference in tone and approach taken by the scientists actually doing climate research (Schneider and Bryson) and the science-writers who are not actively working in the field (Wilcox and Calder — and now Halacy).

It is not surprising that this difference should exist. Research scientists are trained to be critical and questioning, and are usually very cautious about jumping to conclusions too quickly (though some do, of course). This trait tends to make their scientific writings a bit dull for the average intelligent layman, although it should be quickly added that Schneider and Bryson are among the liveliest of scientist-writers.

On the other hand, a science-writer approaches his subject with the eye of the journalist, and may be on the lookout for a good story rather than a presentation of a balanced account. Halacy, in *Ice and Fire?* like Calder, has chosen to write a book whose central theme is the prediction of a global cooling as the beginning of a new ice age — perhaps occurring very quickly. Although he mentions the fact that Calder's book was criticised by many climatologists and other scientists as "irresponsible scaremongering", he has followed the same chilling path: The coming ice age, the slow growth of ice sheets over North America and Europe, the lowering of sea level as the water is trapped as ice on land, the changing patterns of precipitation, and the global scramble for new sources of food as the old ones become unfavourable are all described — almost, it would seem, with relish.

There is a strong counterpoint to this prediction of an imminent ice age, and that is the thought that we might be able to modify or avert it if we tried hard enough. This theme is developed in Part I, which occupies more than half of the book. Halacy wrote a book called *The Weather Changers*, in 1968, and the part on weather (and climate) modification has the same title and seems to be an update on the earlier work, with an emphasis on the subject of *weather* modification — notably rainmaking. There is relatively little said about *climate* modification that would be relevant to the prospect of a coming ice age.

The book is written with an engaging style, but it gives the overall impression of a clever collage of anecdotes, theories, and facts, rather than a development of a main thesis. Furthermore, even a non-expert will notice that he has blurred his timescales cleverly (as did Nigel Calder, whom he quotes extensively), giving the impression that the advent of an ice age could occur in a matter of a decade or so — perhaps it will take a century if we are lucky, he says. This will be recognised as Calder's "snowblitz". Halacy does mention that the periodic fluctuations that have accounted for major natural climate changes are 2,500 to 100,000 yr long (although there seem to be some weaker climate changes associated with shorter periods), but this matter of time-scale is never made clear in talking about the impending ice age. Few climatologists would question the likelihood of a new ice age coming *eventually* — but how many thousands of years from now?

Similarly, he does mention the idea that the burning of fossil fuels and the addition of carbon dioxide to the atmosphere is likely to cause a global warming in the next few decades, and that a "worst case" estimate calls for a warming of over 3°C by the year 2050. This, he concedes, "would play havoc with weather and climate". However, he dismisses the prospect of a warming due to human activities by saying, "There are those who reason that other pollutants stop more incoming radiation and will outbalance the CO_2 to create a cooling rather than a warming trend." This is an idea proposed some time ago by Bryson and others, but there are few left who now subscribe to it.

The expectation of a global warming in the next few decades and centuries, rather than the onset of an ice age, was expressed most authoritatively by the more than 100 experts assembled by the World Meteorological Organization (WMO) for the World Climate Conference in Geneva in February 1979. Said the Declaration of that Conference: "We can say with some confidence that the burning of fossil fuels, deforestation, and changes of land use have increased the amount of carbon dioxide in the atmosphere . . . and it appears plausible that [this] can contribute to a gradual warming of the lower atmosphere, especially at high latitudes . . . It is possible that some effects on a regional and global scale may . . . become significant before the middle of the next century."

Thus, Halacy seems to have a rather poor batting average in his predictions, if we can judge them against current evidence; and one of his statements, presumably written a year or more ago, has already turned out to be quite wrong! "There is no evidence of a global or national [US] climate programme of significance" (p 205). Early in 1979 the US Congress passed the National Climate Program and it is now part of the law of the land; and in May 1979 the Congress of the WMO adopted the World Climate Programme. These are both official programmes being actively pursued on many levels, and the WMO's Programme in particular demonstrates the serious concern of all nations with the problems of climatic variability and climatic change.

Although *Ice or Fire?* deals with a vital set of questions, and although it contains a great deal of information recounted in a lively manner, it is seriously flawed by a combination of emphasis on subjects only remotely relevant to the main theme, and by a main theme that is itself based on a faulty premise. Perhaps if Halacy had written his book a year or two later he would have followed the lead of Wilcox and played on the prediction of a warmer Earth instead of an ice age. That too would have been a good story. □

William W. Kellogg has just completed a 14-month appointment with the WMO in Geneva, where he served as Adviser to the Secretary-General on the World Climate Programme. He has now resumed his post as Senior Scientist at the National Center for Atmospheric Research, Boulder, Colorado.

Geometrical aspects of general relativity

Gravitational Curvature: An Introduction to Einstein's Theory. By Theodore Frankel. Pp. 172. (Freeman: San Francisco, 1979.) £5.20.

TEXTBOOKS on general relativity fall roughly into two classes — the geometrical and the physical. As an example of the former class we have J. L. Synge's fine book *Relativity: The General Theory* (North-Holland: Amsterdam); and in the latter class there is S. Weinberg's excellent *Gravitation and Cosmology* (Wiley: New York). Theodore Frankel's book falls squarely into the geometrical division, as suggested by his title.

Gravitational Curvature starts with a short chapter on special relativity which does no more than set the scene for what is to follow. In chapters 2 and 3 Einstein's equations are approached through the principle of equivalence, the gravitational red shift and Poisson's equation. It is in the essence of the author's treatment that Poisson's rather than Laplace's equation should appear at this stage because throughout he is as much interested in the right-hand side of Einstein's equations

$$R_{ik} - \tfrac{1}{2} g_{ik} R = 8\pi\kappa T_{ik} \qquad (1)$$

as he is in the left, an attitude which is still fairly uncommon.

It is in chapter 4 that the author declares his hand, in a section headed "A Geometric Form of Einstein's Equations", where he rewrites (1) as

$$8\pi\kappa T(\zeta, \zeta) = -\tfrac{1}{2}\varepsilon_\zeta R_{V^3} + \mathrm{tr}(\mathbf{b} \wedge \mathbf{b}). \quad (2)$$

Here ζ is a unit vector at a point p in space-time V^4, and V^3 is any hypersurface normal to ζ; R_{V^3} is the scalar curvature of V^3, and $\mathrm{tr}(\mathbf{b} \wedge \mathbf{b})$ depends on the extrinsic curvature of V^3 embedded in V^4 (ε_ζ is ± 1). What (2) says is that however V^3 may curve at p, the left hand side (which in an older notation is $8\pi\kappa T^{ik}\zeta_i\zeta_k$) depends only on the normal ζ. As an application consider a perfect fluid and let V^3 be a totally geodesic space-like hypersurface (that is, one whose second fundamental form vanishes). The second term on the right of (2) disappears and we have

$$R_{V^3} = 16\pi\kappa\varrho.$$

ϱ being the proper density, which, as the author remarks, is a particularly beautiful consequence of Einstein's equations.

The author has not derived (2) just for fun. On the contrary, he uses this form of the equations repeatedly — to derive the Schwarzschild exterior solution in chapter 5, for the general static spherical mass distribution in chapter 11, for cosmology in chapter 12, and for other applications. In the remaining chapters are treated the perfect fluid, equations of motion, light rays, and, in some detail, electromagnetism in special and general relativity.

The treatment throughout is quite advanced. No introduction to tensor calculus or differential geometry is given, and there are no examples or exercises to help the student. Not merely is a knowledge of tensors assumed, but the reader is expected to be acquainted with differential forms, and the index-free notation as in (2) above. *Gravitational Curvature* is therefore not really a textbook. The author writes in the Preface that "ideally, the material here would be given as the third quarter of a year course devoted to manifolds and Riemannian geometry", but it seems to me that the first two quarters of such a course would be pretty indigestible.

Who then will benefit from the book? I believe that to trained relativists it should cast a refreshing new light on the geometry of their subject. It would be nice to think that there will be some enlightenment passing in the other direction, by which I mean that differential geometers looking at the book may see how close relativity is to their subject, and even turn their attention to it for a while.

Fludd debates

Robert Fludd: Hermetic Philosopher and Surveyor of Two Worlds. By J. Goodwin. Pp. 96. (Thames and Hudson: London, 1979.) Paperback £2.95.

CHIEFLY remembered today as the target of polemical attacks by seventeenth-century men of science like Kepler, Mersenne and Gassendi, Robert Fludd (1594—1637) was among the most famous physicians and occultists of his time. In an interesting paper, published in English translation in 1955 ('The Influence of Archetypal Ideas on the Scientific Theories of Johannes Kepler'), the physicist Wolfgang Pauli showed that the Fludd—Kepler debate could not simply be regarded as one between an obscurantist occultist and a modern 'scientist'. The polemic of Mersenne and Gassendi more directly rejected Fludd's ideas in the light of the corpuscularian and mechanistic philosophies then being developed. However obscure and repellent they may now seem, some grasp of Fludd's doctrines is essential for a genuine historical understanding of an influential current which was to be vanquished and eclipsed by the science of Galileo and Descartes.

Fludd's works are rare and have become expensive collectors' items chiefly for the beautiful engravings with which they were adorned by de Bry and Matthieu Merian in their sumptuous Frankfurt editions. A study of the engravings is essential for making it possible to penetrate Fludd's strange and fantastic cosmology. That has been made much easier by Dr Joscelyn Goodwin, a musicologist, who has brought together 120 of the plates in a well-printed and reasonably priced book.

According to Dr Goodwin in his biographical introduction, the chief value of his collection of engravings lies in reminding us "of the possibility, indeed the imminence, of a cosmic view free alike of the myopia of materialism and the absurdities of naive spiritualism'. But his full bibliography will usefully guide the reader to other recent sources in which an attempt has been made to place the Fludd debates within the scientific and philosophical *milieu* of the seventeenth century.

P. M. Rattansi is Professor of the History and Philosophy of Science at University College, London, UK.

Biological foundations of sensory processing

Sensory Processing, Perception, and Behaviour. By R. B. Livingston. Pp. 106. (Raven: New York, 1978.) Paperback $11.05.

IN his preface to this mercifully slim volume, which was aimed originally at psychiatrists, the author says his intention is "to present the main biological foundations for perception, judgement, and behavior, in an evolutionary and developmental context.". The ground is covered in 83 pages, but the ride is uncomfortably rough.

The book is extraordinarily hard to read, and I had great difficulty in making sense of parts of it. The principal problem is the pretentious prose, which actively hinders comprehension. Here are two representative samples: "Humankind is presently in need of experiencing unprecedented perceptual, judgemental, and behavioral discontinuity, from prior to new forms of imaging"; and "similarity of views are attractive to one another, leading to greater introversion of perspectives and greater societal self-righteousness".

The other difficulty is the organisation; although the book is divided into four chapters, Behavior and Evolution, Perception, Sensory Processing, and Sensation, the order of topics in the last three is arbitrary, and seems quite confused. I often failed to grasp the thread of an argument simply because the discussion was so disconnected.

Underneath these deficiencies, I found the work interesting, principally because its broad coverage introduced me to some unfamiliar observations and ideas. However, I valued the book less for the author's synthesis of general principles than for the provision of references and pointers to other reading.

The chapter on Behavior and Evolution sets the tone for the rest of the monograph. Here Livingstone makes the point (not new to psychologists) that the idea of tight connections between sensory stimulus and behavioural response is an impoverished view of what controls behaviour. He then goes on to develop the argument that man's flexible and complex behaviour depends upon his development of a large brain, which is only possible if infants are immature at birth, which in turn means that most of man's skills have to be learned. So man becomes the flexible animal. These arguments are plausible but, in common with many made in the book, are not developed thoroughly enough to permit careful examination.

The chapter on Perception introduces the idea that our capacity to structure our sensory input depends on our having, in our brains, adequate models of the world. Here Livingston touches upon ideas that have been influential in perceptual psychology for nearly forty years, but he does not acknowledge this work. His discussion also neglects many worthwhile and exciting developments in 'Cognitive Psychology', and the insights into perceptual processing that have been obtained from work on the recognition of objects by computer programs. The result is a naively optimistic view of the ease with which psychological phenomena can be related to physiological events in the brain.

The chapter on Sensory Processing contains an odd mixture of topics that are not well integrated. Lateral Inhibition is included, as might be expected, but so is a summary of the psychology of perpetual development, which I found surprising. I had expected to see some discussion of broad principles that are common to the operation of the different sensory systems —for example, Müller's doctrine of specific nerve energies and its modern counterpart, the single unit doctrine—but nothing of the sort is mentioned. Moreover, there is no discussion of the sensory codes used for the transmission of information. There are interesting sections on feedback and feedforward control mechanisms, and on the centrifugal control of afferents, but again the author fails to place these in any larger context.

The final chapter, on Sensation, is a good deal more specific than the others, and the major part of it is devoted to a straightforward review of the physiology and anatomy of the different receptor systems and their associated pathways. I was again disappointed that the author did not bring out common principles in their operation.

Livingston's aim was to provide a coherent view of how modern biology can help us better understand some old problems in philosophy and psychology. He falls short of his goal.

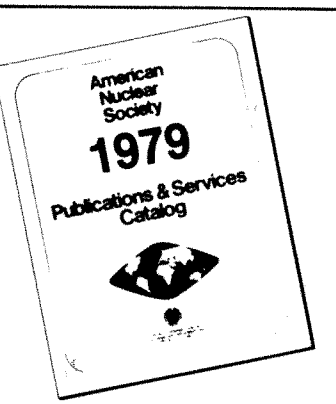
Victorian medicine

The Scientific Revolution in Victorian Medicine. By A. J. Youngson. Pp. 237. (Croom Helm: London, 1979.) £9.95.

THE bookshop browser whose eye is caught by this title might well turn to the preface to learn about the aims of the book and to the concluding chapter to find a summary of the content of the book. Impressed, he might take it home, where a more leisurely inspection would reveal a strangely unrelated text sandwiched between the preface and conclusion.



We are wisely advised in the preface to avoid the trap of thinking that all who resisted new ideas were merely dull or obscurantist, but the sandwich filling falls into this very trap: "pre-scientific" medical men suffered from "slovenly thinking"; they "did not know enough medicine" (the author means *our* medicine); Sir Henry Holland was "not altogether foolish" in following Celsus' advice about the need for cheerfulness in the sickroom — that of six prime ministers and two queens, in Sir Henry's case — but in doing so he "seriously underestimates the importance, or at least the potential importance, of scientific and technical [*viz*, twentieth century] medicine".

The modern observer of the early nineteenth-century hospital might well be "struck with the utmost astonishment" if he was a modern doctor, but, I suggest, if he were a modern historian he would understand the absence of precautions when the threat was not known; he would have doubted whether some speculations of the time were "sensible" simply because they were later proved to be right; and he would certainly have disagreed with the notion that the renaissance idea of the generation of the barnacle goose was a *denial* of *modern* biology.

The concluding chapter attempts a formal analysis of the reasons for resistance against new ideas, and a number of interesting points are raised. These should have been tied in more closely with the previous chapters, where the examples that illustrate the general statements are comparatively standard accounts of the introduction of anaesthesia, antisepsis and related topics. These accounts differ from others largely in the author's dependence on the *Lancet*. To have these accounts together in one volume is convenient, at least, and the historical style might well prove attractive to those with an interest in the history of their profession.

Plant protection

The Plant Protection Discipline: Problems and Possible Developmental Strategies. By W. H. Sil, Jr. Pp. 190. (Wiley: Chichester, UK, and New York, 1979.) £17.75.

THE title of this book is misleading, although the subtitle does imply that it is concerned not with a factual account of the subject, but with a discussion of certain aspects. It is essentially a series of essays which consider the problems caused by pests, diseases and weeds in the major agricultural crops of the world, the ways in which research, development and advice are used to bring them under control, and the conflicting interests involved.

The problems illustrated are almost exclusively American, although there is some reference to the work in developing countries of international agencies such as FAO and the Ford and Rockefeller Foundations. There is an excess of quotations which are so numerous and conflicting that it is difficult to discern the author's own views. Indeed he apologises for them in his introduction: "This is not a scientific treatise. Rather it is a compendium and summary of the thoughts of the leading proponents or opponents of this new discipline. Consequently, there are many quotations, far more than most scientists, including the author, might prefer."

The book is intended for "government officials, administrators and leaders in the various sub-disciplines." It argues the case for an interdisciplinary approach to the increasingly serious problem of crop losses from pests and diseases. This subject is certainly one of urgency and the reader is given a comprehensive account of a situation which has arisen chiefly from increasing concern about the pollution of the environment by pesticides and an increase in the incidence of resistance and tolerance of pests and diseases to chemical control. (A recent report from the UN Environment Programme shows that the number of insect and mite species which have developed tolerant strains increased from 182 in 1965 to 364 in 1977.) The crop losses caused by pests, diseases and weeds are serious and worldwide, and the sophisticated systems of monoculture in the developed countries are as dependent on effective pests and disease control as are the more primitive systems of the developing countries which are seeking to exploit the improved varieties bred specifically for the Green Revolution.

To meet this challenge Dr Sil maintains that there is a need for a new profession to educate 'general practitioners' of plant protection. He complains with some reason and factual support that agriculture is a low prestige subject, especially in developing countries and that applied research in agriculture is less prestigious than pure research. He distinguishes differences in attitudes between entomologists and plant pathologists, a distinction which is not nearly so significant in Europe as it seems to be in America. There is brief reference to legislation governing the use of pesticides and schemes for certification of pesticides and those who apply them. There is a lengthier consideration of the need for cooperative efforts between the various disciplines and agencies involved and at times, the author becomes obsessed with the technical jargon of 'crop protection', 'plant protection', 'pest management', 'Biological control', 'integrated pest control' and so on, so that he loses sight of his main theme in the minutiae.

The remaining chapters of the book are devoted to a consideration of possible organisational strategies as they relate to collaboration between official research and advisory organisations and the chemical industry. The emphasis throughout is on the integration of education, research and advice.

There is little new in this treatment but the book serves a useful purpose in bringing together many topics that are of current worldwide concern. Interesting though the discussion may be, however, the readership of the book is likely to be very limited. It is hardly a book of reference because both the situation and attitudes are changing all the time; and it is expensive for what it is.

● Paul Colinvaux's *Why Big Fierce Animals are Rare* (Princeton University Press: New Jersey; for review, see *Nature* **273**, 787; 1978) will be published in the UK in November by George Allen and Unwin (London) at £6.50.

HLA and H-2

HLA and H-2: Basic Immunogenetics, Biology and Clinical Relevance. By H. Festenstein and P. Démant. Pp. 215. (Edward Arnold: London, 1978.) Paperback £9.

TRANSPLANTATION immunology has evolved in an attempt to understand, and prevent, rejection of foreign grafts. Although we may have been getting closer to this goal, the impact of this research has not been restricted to that old dream of restorative medicine but has contributed fundamentally to a better understanding of vertebrate genetics and immunological phenomena in general, ranging from tumour immunology and serology to such complex phenomena as immune response regulation and the fascinating linkage between susceptibility to disease and major transplantation antigens.

This booklet on HLA and H-2 covers this wide area in a short and accessible way. It is intended for the many clinicians and immunologists who do not have the time, or courage, to study the encyclopaedic treatises on H-2 by J. Klein or by Snell, Dausset and Nathenson. Taking transplantation immunology as "art pour art" the book is teaching a great deal: How to perform HLA typing economically and reliably, how to inbreed mice, the grand rules of serology and genetic analysis, how to cope with statistics of gene linkage, that complement factors and other MHC products may have interesting things in common, some ideas about the mysterious MIs locus or the L antigen in mice, a simple method to use sperm as Lad typing cells, and a great number of most helpful tables on various antigen systems, frequencies of antigenic specificities, cross-reactivities, the newest rules in terminology and designation of specificities. Although the booklet has a small format, it is really an extended review, and it has been difficult to treat the immense abundance of facts and speculations on HLA and H-2 even in 200 pages. That the intended brevity has, except for MHC-coded *Ir* genes, left out some of the recent insights into the biological role of major histocompatibility gene products in defining T cell effector function, restriction specificity and responsiveness is (and my view is obviously biased) a pity. Some explanation of the probably real biological functions of major transplantation antigens might make it easier for the reader and student to get a feeling for the linkage between cell-mediated immunity against intracellular parasites (for example, viruses) and graft rejection (with all consequences for immunosuppressive therapy), for polymorphism (really the basis for transplantation reactions), and associations of disease susceptibilities and major histocompatibility antigens. However, people concerned with the practical consequences of major transplantation antigens in graft rejection are interested in the hard facts, methods of analysis and their correct evaluation of everyday experiments in the clinic or the laboratory, rather than in philosophical discussions on evolution and function of major transplantation antigens. For these practical aspects this booklet is of great value to students and practitioners in transplantation immunology and will serve as excellent and handy *vademecum*.

A Selection of Physics Texts

Modern Atomic Physics
Fundamental Principles
P. Cagnac and J-C. Pebay-Peyroula
Translated by J. S. Deech

This introductory volume discusses the crucial experiments that demonstrate the limitations of the classical theory, sets down the fundamental laws governing the internal structure of atomic systems, and surveys current experimental work. Special attention is also given to orders of magnitude calculations.
1975, £5.95

Galaxy Formation: A Personal View
John Gribbin

The debate about the structure and origin of the Universe has attracted a diversity of plausible but conflicting explanations. In this personal view of galaxy formation, Dr Gribbin criticises theories and examines current research and attitudes.
1976, £5.95/£2.95

Atomic Dynamics in Liquids
H. N. March and M. P. Tosi

A difficult and challenging area of physics has here been lucidly and authoritatively explained. This text deals with the dynamics of electrons in liquids at a level suitable for research workers and advanced students.
1976, £25.00

Thermal Physics
P. C. Riedi

An introductory text which places roughly equal emphasis on classical macroscopic thermodynamics and statistical mechanics, with a pronounced bias towards discussing applications.
1976, £10.00/£4.95

Forthcoming:

Thermodynamics of Irreversible Processes
B. H. Lavenda

A clear exposition of the basic formalism applicable to non-linear thermodynamic processes, written at a mathematical level accessible to physicists, theoretical chemists and biologists. Examples are given showing the application of the formalism in various physical and biological situations.
December 1977, £12.50.

Inspection copies of titles costing less than £6 are available from Miss Kim Mitchell, Dept P3(N), The Macmillan Press, Little Essex Street, London WC2R 3LF

To order a copy of any of these books, please send the correct amount, plus 50p per volume carriage, to Technical Book Services, P.O. Box 79, Maidenhead, Berkshire SL6 2EG

APPOINTMENTS VACANT

UNIVERSITE DE LAUSANNE
Faculté de Médecine

Un poste de 4ème professeur de physiologie est à pourvoir. Entrée en fonction à convenir. Les candidats doivent envoyer leur curriculum vitae, liste de publications et 3 références au prof. H. Van der Loos, Institute d'Anatomie, Bugnon 9, Ch-1011 Lausanne-CHUV, Suisse, auprès duquel ils peuvent se renseigner.

W296(A)

UNIVERSITY OF WARWICK

POSTDOCTORAL RESEARCH FELLOW IN BIOLOGICAL SCIENCES

To join a group led by Dr A Colman of the Department of Biological Sciences, on a project involving the secretion of mouse immunoglobulins by oocytes and embryos of *Xenopus laevis*. Previous experience in messenger RNA isolation and purification would be an advantage, but not a necessity. The successful candidate will be required to use various techniques involved in the *in vitro* and *in vivo* translation of messenger RNAs and the immunoprecipitation of the products already in use in the laboratory. The post is supported by the Cancer Research Campaign from 1st October, 1979, renewable on an annual basis, but a suitable applicant may start at a later date.

Starting salary on the IA scale: £4,333 (£5,777) — 7,521 pa plus USS.

Further particulars can be obtained from Dr A Colman in the Department of Biological Sciences. Application forms from the Academic Registrar, University of Warwick, Coventry CV4 7AL quoting ref no 1/A/79. 2900(A)

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL
(University of London)
Denmark Hill
London, SE5 8RX
DEPARTMENT OF MEDICAL MICROBIOLOGY

A Postgraduate Research worker is required from 1st October 1979 or as soon as possible thereafter, to participate in an MRC funded project investigating the interactions between interferon and natural killer (NK) cells. Candidates should possess a good honours degree and the successful applicant will be expected to register for a higher degree.

Salary will be on the University scales for Research and Analogous staff, according to age, qualifications and experience. For further information please contact Dr Mary Anderson on 01 274 6222 Ext 2480.

Applications, giving full curriculum vitae and the names and addresses of 2 referees should be sent to the Secretary of the Medical School. Closing date 14th September, 1979. 2929(A)

UNIVERSITY OF LONDON GOLDSMITHS' COLLEGE
New Cross, London SE14 6N
School of Science & Mathematics
BIOLOGICAL SCIENCES DEPARTMENT
TEMPORARY LECTURESHIP IN ZOOLOGY

Applications are invited for a tempor lectureship in Zoology, in the Departm of Biological Sciences. The Departmen looking for candidates with good qua ications in cell biology and special inter in cytology/histology but is also prepa to consider applications with interests other fields of Zoology.

The appointment will be from September, 1979 or as soon after possible until 30th August, 1980 with possibility of an extension for a seco year.

Salary on scale £4,470 × 12 increments £7,701 per annum plus £474 Lond Allowance.

Write for further information to Personnel Officer, to whom applicatic should be sent by 14th September, 1979 2948(A

Coal Scientists—

Carboniferous Palynology

The National Coal Board is seeking an Honours graduate with research experience in carboniferous palynology, to based at the Regional Laboratory at Wath Upon Dearne, South Yorkshire.

The successful candidate will assist with the solution of stratigraphical problems connected with exploratory boreholes and the identification and correlation of coal seams at colleries using palynological methods. It will also be necessary to undertake research towards refining the existing palynological schemes for zoning the Coal Measures. A scanning electron microscope is available within the Department.

The appointment will be made within an inclusive salary range of £6,000 – £7,500. Details of other benefits, including superannuation, annual leave, etc., will be explained at interview.

Please apply, with full career details and qualifications quoting reference AA265, to:

NCB **Headquarters Staff Manager (Doncaster), National Coal Board, Coal House. Doncaster DN1 3HG.**

2916(A)

HERIOT-WATT UNIVERSITY
Riccarton, Edinburgh
DEPARTMENT OF CHEMISTRY
The Synthesis of New Antibiotics

(a) POSTDOCTORAL RESEARCH ASSOCIATE
(2 years)

Candidates must be highly qualified, a have a thorough background in orga synthesis. The programme will involve synthesis of a new group of potential a biotics; and will encompass the chemis of β-lactams and peptides. Salary £4,91 £5,199, plus related superannuati benefits.

(b) RESEARCH TECHNICIAN
(2 years)

The successful applicant will h experience of organic synthesis and work on the above programme collaboration with the postdocto worker, but pursuing independ research. An honours degree is prefer and registration for a higher degree ma possible. Salary £3,513 to £3,609, related pension benefits.

Applicants should send a curricul vitae as soon as possible to Dr. M. Campbell, Department of Chemist Heriot-Watt University, Riccart Currie, Midlothian EH14 4AS and sho arrange for referees to send references. 2893(A

THE UNIVERSITY OF LANCASTER

DEPARTMENT OF BIOLOGICAL SCIENCES

RESEARCH ASSISTANT

Applications are invited for a post to work in the Electron Microscope Unit (Mr K Oates) on the low temperature microscopy of articular tissues in health and disease. The appointment, supported by the Medicl Research Council, is tenable for two years in the first instance. The research programme has been developed in close association with the Department of Histopathlogy (Professor D L Gardner) University of Manchester, co-holder of the relevant MRC grant.

Applicants should have a good honours degree in an aspect of the biological sciences, and they should have a sympathetic interest in the manipulative skills of instrument technology. The possibility exists to study for a higher degree. Salary on the scale £3,775 to £5,488.

Further particulars may be obtained quoting reference L156/B) from the Establishment Officer, University House, Bailrigg, Lancaster, LA1 4YW to whom applications (6 copies) naming three referees, should be sent not later than 21 September, 1979. 2943(A)

QUEEN ELIZABETH COLLEGE
Kensington
(University of London)

HEAD TECHNICIAN GRADE 7

CHEMISTRY DEPARTMENT

Applications are invited for Head Technician (Grade 7) in the Chemistry Department. Applicants should have appropriate qualifications and experience, including the supervision of technical staff, wide laboratory experience and the maintenance of instruments.

Salary within range £5,162 to £5,737 pa inclusive of London weighting.

Application forms from Mrs G Howard, Administrative Assistant, Queen Elizabeth College, Campden Hill Road, London W8 7AH. Tel: 01 937 5411 ext 499. 2940(A)

MACDONALD CAMPUS OF McGILL UNIVERSITY

DEPARTMENT OF PLANT SCIENCE

ASSISTANT PROFESSOR IN PLANT SYSTEMATICS

Applicants invited for a teaching and research tenure-stream position in *Plant Systematics*. Teaching duties will include undergraduate courses in Plant Systematics, Morphology and General Biology of Organisms (plant oriented), and graduate course in Advanced Systematic Botany or other as developed by the appointee.

The appointee will also hold the position of Curator of the McGill Herbarium with approximately 100,000 specimens. Appointment will be made at the Assistant Professor level. Applicants must have a PhD or expect to receive it shortly in plant science with a major in plant systematics/botany.

A complete curriculum vitae, a short statement of research interest and names of three referees should be sent to Prof W F Grant, Chairman, Selection Committee, Department of Plant Science, Macdonald Campus, McGill University, Ste. Anne de Bellevue, Quebec, H9X 1CO, Canada. Closing date for application, 1 November 1979 or later if position not filled.

W304(A)

CAREERS IN SCIENTIFIC COMPUTING AND ELECTRONIC ENGINEERING

Challenging opportunities to work on:

MICROPROCESSORS NETWORKS
REAL TIME PROGRAMMING LOGIC DESIGN

Daresbury Laboratory is developing major national facilities in the fields of computer networking, atomic, molecular and biological sciences and nuclear physics. The exploitation of these facilities requires first-class computing support. Computers at the laboratory include an IBM 370/165, GEC 4070 PDP-11s and Interdatas.

COMPUTER NETWORKS

Development and support of communications software for interactive terminal, graphics and remote job entry access to the SRC's computing centres using microprocessor based communications hardware and mini-computer pocket switches and front end processors.

DATA ACQUISITION

Programmes are required for the development of data acquisition systems using LSI and PDP-11 computers connected to an IBM 370/165. There are opportunities to work with large and small systems in a stimulating scientific environment. Relevant programming experience would be an advantage but is not essential.

LOGIC DESIGN

Interface design for mini-computers using the latest microprocessor techniques, also communications interfacing to remote data processing. Specialised design of data acquisition systems.

Applicants, of either sex, should have a good honours degree in a relevant scientific discipline. Appointments will be made depending on qualifications and experience at SO level.
Scientific Officer £3,289 - £5,085 (salaries are currently under review)
Closing date: 7 September 1979
Please write or telephone: Warrington 65000 Ext. 467, for an application form quoting reference DL/694/

The Personnel Officer
DARESBURY LABORATORY
Science Research Council
Daresbury, Warrington WA4 4AD

2926(A)

TECHNICIAN/ RESEARCH OFFICER

to head a small fermentation unit aimed at the production of enzymes. Preference given to someone interested and experienced in isolation of enzymes. Degree/HNC. Salary range £3,600 to £5,250.

For further information and application form, write or telephone to Miss S M Hurley, Imperial Cancer Research Fund, Lincoln's Inn Fields, WC2 on 242 0200 ext 305 quoting ref BG1. 2932(A)

ANTHONY NOLAN Bone Marrow Research Laboratories, St. Mary Abbots Hospital, Marloes Road, London W8. Senior grade person required to take technical and partial administrative charge of these laboratories mainly responsible for tissue typing bone marrow volunteer donors. Applicant should be a senior graduate or senior technician with considerable experience of tissue typing. Salary on higher University Biochemist or Whitley council MLSO scales as appropriate. Apply in writing to Dr D C O James, Blood Transfusion Unit, Westminster Hospital, Dean Ryle Street, London SW1. 2915(A)

UNIVERSITY OF READING

DEPARTMENT OF SOIL SCIENCE

Applications are invited for a Lectureship in Soil Science with responsibility in soil physics or mineralogy or soil biochemistry.

The appointment will be made within the first five points of the Lecturer salary scale (£4,333 to £5,488 per annum).

The person appointed should take up duties on 1 January 1980.

Further information may be obtained from the Registrar (Room 214, Whiteknights House), The University, Whiteknights, Reading RG6 2AH, by whom applications should be received not later than 30 September, 1979.

2895(A)

Synthetic Organic Chemists

Salary Range £4,500-£6,500 p.a.

The Pharmaceuticals Division of Imperial Chemical Industries is seeking a small number of recent chemistry graduates who would enjoy the challenge of working in organic synthesis directed toward medicinal targets. A good honours degree is essential and previous experience of organic synthesis desirable. Successful candidates will operate with a fair amount of independence whilst remaining under the overall guidance of a Ph.D chemist and have the opportunity of tackling a variety of chemical problems.

The Division's research laboratories are situated in pleasant surroundings but within easy reach of main road and rail routes. Conditions of service, salary and assistance given to married staff in moving house are designed to attract and retain staff of high calibre.

Applications in writing should quote reference D.B.6 and should be addressed to:

ICI

Mrs D. Bass,
Assistant Personnel Officer,
I.C.I. Pharmaceuticals Division,
Mereside Research Laboratories,
Alderley Park, Macclesfield, Cheshire.

2949(A)

PRESIDENT

DESERT RESEARCH INSTITUTE

Applications and nominations are invited by the Board of Regents, University of Nevada System, for the position of President of the Desert Research Institute.

This autonomous, statewide division of the University System conducts research programs in Atmospheric Sciences, Water Resources, Energy Systems, Social Sciences and Bioresources, funded by both governmental and private sources. Established in 1959, the Institute has a current annual budget of about six million dollars and a faculty of 90 professionals. There is a close association between institute research and University graduate programs. The President reports directly to the Board of Regents, with a position equivalent to the Presidents of the two University campuses. The present incumbent is retiring.

Qualifications include demonstrated leadership abilities, a doctoral degree, a background in scientific research, a distinguished record of intellectual achievement, a broad background in the funding, conduct and management of research, and proven effectiveness in the areas of governmental, university and community relations.

Applications will be accepted until October 1, 1979. The position will be filled at the convenience of the candidate, but no later than July 1, 1980.

To apply, or for further information, contact:

Presidential Search Committee
Desert Research Institute
University of Nevada System
PO Box 60220
Reno, Nevada 89506

AN EQUAL OPPORTUNITY/
AFFIRMATIVE ACTION EMPLOYER

W300A

POSTDOCTORAL
RESEARCH FELLOW

PROTEIN METABOLISM

Applications are invited for an appointment of up to two years, to work with Professor J C Waterlow at the Clinical Nutrition & Metabolism Unit, St Pancras Hospital, on studies of the regulation of protein synthesis and breakdown in animal tissues. The salary will be in the 1a range for research staff, £4,260 to £7,145 (£4,333 to £7,521 from 1 October 1979) plus £502 London Weighting.

Applications, consisting of full curriculum vitae and naming two referees, should be sent to Secretary (A1), London School of Hygiene & Tropical Medicine, Keppel Street, London WC1E 7HT.

2913(A)

UNIVERSITY
OF BRISTOL

DEPARTMENT OF BIOCHEMISTRY

Applications are invited for a post-doctoral appointment, supported for three years by the Medical Research Council, to work on the glycoproteins of human mucous secretions, particularly the bronchial secretions of chronic bronchitics and asthmatics.

The work will involve preparation of the glycoproteins, physico-chemical characterization, and a study of the products of limited degradation. Candidates should have experience in protein chemistry; an interest in physical biochemistry would be advantageous. Initial salary £4,232 (Range 1A), to commence 1 October 1979 or as soon thereafter as possible.

Enquiries should be addressed to Dr J M Creeth, Department of Biochemistry, University of Bristol Medical School, Bristol BS8 1TD. 2933(A)

UNIVERSITY
OF ST ANDREWS

AND APPLIED SCIENCE

to work on the study of polymer subst interactions. The research will involve characterization of metal substrates us ESCA and XPS and the characterisatio the effects of various surface treatment the adhesion of a polymer film t pretreated substrate. This project associated with studies of polyme materials as electron beam developm agents.

The post, which is supported by SR(for two years.

Commencing salary on Range 1A of national salary structure for research analogous staff up to £4,910 per ann with placing according to a qualifications and experien Superannuation benefit.

Applications naming two referees including a curriculum vitae should be s (quoting R34/79) to Dr R A Pethr Department of Pure and Appl Chemistry, Thomas Graham Building, Cathedral Street, Glasgow G1 1XL. 2930(A

UNIVERSITY OF THE WITWATERSRAND
Johannesburg

DEPARTMENT OF PHYSIOLOGY

Applications are invited from suitably qualified persons for appointment to the posts of:

1. SENIOR LECTURER/ LECTURER (two posts)

2. RESEARCH FELLOW

Applicants for these posts should have a medical or veterinary degree or a PhD in physiology, Biochemistry, Pharmacology, zoology or any other biological field.

The Lectureships and Senior Lectureships involve teaching undergraduate and graduate medical and science students, research, and participation in the administrative work of the department. There is no restriction on the field of interest of applicants.

The Research Fellow will be involved in an on-going programme of research, at a biochemical, pharmacological and physiological level, in cardiovascular physiology and health and disease. Applicants with a background in protein biochemistry, radio-ligand binding studies, or adrenergic pharmacology are particularly invited to apply.

The salary range for Lecturer is R8,100 to R16,800; for Senior Lecturer is R15,000 to R17,400 and for Research Fellow is R8,100 to R13,200 per annum (£1 = R1.89 approx).

The University's policy is not to discriminate in the appointment of staff or the selection of students on the grounds of sex, race, religion or colour.

Further particulars relating to this practice and to the above posts are included in an information sheet obtainable from the London Representative, University of the Witwatersrand, Chichester House, 278 High Holborn, London WC1V 7HE, or from the Registrar, University of the Witwatersrand, Jan Smuts Avenue, Johannesburg, South Africa, with whom applications should be lodged by 15 September, 1979. 2928(A)

UNIVERSITY COLLEGE LONDON
DEPARTMENT OF PHARMACOLOGY

POST DOCTORAL RESEARCH ASSISTANTS

Two Post-doctoral research assistants required for work on cholinergic transmission supported by 5-year MRC Programme Grant under the supervision of Professor H. P. Rang and Dr. D. Colquhoun. One post is for an electrophysiologist (with experience of microelectrode recording) to work initially on voltage clamp studies on neuromuscular and ganglionic synapses, and eventually to develop new recording techniques. The laboratory is well equipped for electrophysiological recording and on-line computer analysis.

The other post is for a physiologist or biochemist to undertake mainly biochemical work on transmitter synthesis and release, receptor labelling, and membrane permeability changes evoked by neurotransmitters.

Those appointed will form part of a group of about seven scientific staff, which is to be set up at University College in newly built and newly equipped laboratories. Starting salaries will be about £5,307 (inc. London Allowance). Applicants should send full curriculum vitae and names of two referees before 31 August 1979 to Professor P. Rang, Dept. of Pharmacology, University College London, Gower St, London WC1E 6BT. 2911(A)

PRINCIPAL SCIENTIFIC OFFICER
(Tidal Waters)
Grade 12

(£9,333 to £10,059 plus £312 supplement)
(Salary Award Pending)

An energetic and enthusiastic Scientist (male or female) is required to lead a small team of Tidal Water specialists based at the Headquarters of the Welsh Water Authority at Brecon and also to be responsible for advising on and co-ordinating the work programmes of Divisional Tidal Waters Staff. The duties will include the setting of quality objectives. Advice on the formulation of consents to discharge. Advice and co-ordination of monitoring programmes to acquire routine physical, chemical and biological data from estuaries and coastal waters. Planning, directing and evaluating the hydrographic surveys and environmental appraisals necessary for the effective management of disposals of wastes to tidal waters. Liaison with staff of the Directorates of Operations and Resource Planning concerning remedial works. Involvement with existing and potential industrial dischargers with regard to their effluents.

The successful applicant will report to the Assistant Director of Scientific Services (Water Quality) and will represent the Authority on a number of national working parties.

Applicants should have a degree or equivalent in a Marine Science, proven management ability and considerable experience of pollution control in tidal waters.

This post carries a Regular User Car Allowance and Disturbance Allowances will be paid in appropriate cases.

Application forms are available from:

The Assistant Personnel Officer (Ref. 320)
Welsh Water Authority, Cambrian Way
Brecon, Powys LD3 7HP
Telephone: Brecon (0874) 3181 Extn 373
Closing Date: Wednesday 29th August, 1979

2934(A)

WELSH WATER AUTHORITY
AWDURDOD DWR CYMRU

UNIVERSITY OF WARWICK

POSTDOCTORAL RESEARCH FELLOW in Biological Sciences

To join a group led by Dr J Bennett in the Department of Biological Sciences, on photocontrol of thylakoid structure and function in higher plants. The successful candidate will explore the role of thylakoid protein phosphorylation in photosynthesis. Previous experience in physical or enzymic aspects of the light reactions of photosynthesis would be an advantage. The post is supported by the Science Research Council from 1st October, 1979 for two years, but a suitable applicant may start at a later date. Salary on the 1A scale: £4,333 (£5,777) to £7,521 pa plus USS.

Further particulars from Dr J Bennett, Department of Biological Sciences. Application forms from the Academic Registrar, University of Warwick, Coventry CV4 7AL quoting Ref No 1/3A/79. 2902(A)

KENNEDY INSTITUTE OF RHEUMATOLOGY

POST DOCTORIAL RESEARCH ASSISTANT IN DIVISION OF BIOCHEMISTRY

Applications are invited for the post of Research Assistant for the further development of a project investigating the molecular basis of the pathological changes in connective tissues associated with articular joint degeneration (osteoarthritis).

The work is fundamental and forms part of an integrated programme of connective tissue research within the division of biochemistry (Head, Dr Helen Muir, FRS).

Previous experience of connective tissue or protein biochemistry, proteolytic enzymes or tissue culture technique would be an advantage. The position is funded in the first instance for three years; salary in the range of £4,835 to £5,701.

Applications enclosing a curriculum and vitae and the names of two referees should be sent to Dr Helen Muir, The Director, Kennedy Institute of Rheumatology, 6 Bute Gardens, Hammersmith W6 7DW. 2945(A)

ROYAL POSTGRADUATE MEDICAL SCHOOL
DEPARTMENT OF IMMUNOLOGY

RESEARCH/SENIOR RESEARCH OFFICER

required for the remaining 2 years of an MRC funded project concerned with a clinical and experimental study of immunological function and graft versus host disease following bone marrow transplations, undertaken jointly between the Immunology and Haematology Departments at the Royal Postgraduate Medical School, Hammersmith Hospital. The post becomes vacant October 1st 1979, but an overlap of 2-4 weeks with the present holder is desirable and could be arranged.

Starting salary up to £5,777 a year. Applicants should have experience and preferably a higher degree in cellular immunology,and be familiar with tissue culture techniques.

Application forms and further particulars may be obtained from the Royal Postgradualte Medical School, Personnel Office, 150 Du Cane Road, London W12 0HS quoting ref no 21/200/N.

Closing date: 10th September 1979. 2873(A)

BIOGEN S.A.

a young company engaged in basic and applied research in the field of molecular biology and microbiology, and with the objective of utilizing the potential of genetic engineering for the production of substances of commercial and medical interest in such areas as health care, agriculture and energy, is inviting applications from

SENIOR AND JUNIOR SCIENTISTS

with experience in molecular biology, nucleic acid biochemistry and microbiology,

for its **Research Laboratory in Geneva,**

Switzerland.

Excellent working conditions, in close contact with leading scientists from Europe and the US.

Salary scale: Group Leaders = SFr 60-85,000, Research Associates = SFr 35-55,000.

Applicants with real interest in both basic research and its applications should send their curriculum vitae (with a description of previous experience and a list of publications) to BIOGEN Laboratory, 3 Route de Troinex, 1227 Geneva, Switzerland. W248(A)

THE BRITISH FOUNDATION FOR AGE RESEARCH

has funds available and invites applications for support of proposed research projects in ageing or relevant to the elderly.

Please write for application form to:

The Director,
The British Foundation for Age Research,
49, Queen Victoria Street,
London, EC4N 4FA

Closing date for applications: Monday, 18 October, 1979.
2903(A)1

THE MULTIPLE SCLEROSIS SOCIETY

Invites applications for three

Career Development Posts at senior lectureship level in multiple sclerosis research.

The positions will be offered in established M.S. Research Centres.

Applicants for these posts should be proposed by another research worker or person with an association with M.S. research.

A summary proposal of the project should be submitted in the first instance.

The application to be based on an MRC programme grant application.

Laboratory site at which proposed project will be carried out to be indicated in the application.

All applications will be considered by the Society's Medical Research Advisory Committee.

Applications to be sent to: The General Secretary, Multiple Sclerosis Society, 4 Tachbrook Street, London, SW1J 1SJ. 2894(A)

UNIVERSITY OF OTTAWA

DEPARTMENT OF BIOCHEMISTRY

POSTDOCTORAL RESEARCH ASSISTANTS

Two recent PhD graduates required to join research group working on plant protein utilization. An enzymologist with experience preferably in cereal chemistry or plant physiology is needed for characterization of lipase in high-protein oats during maturation and storage. A microchemist experienced in stain development is needed to study localization of phytate, glucosinolates, etc in rapeseed.

Research involves collaboration with the food industry and the Food Research Institute of Agriculture, Canada. Salary minimum $12,200.

Please apply to Dr I Altosaar, Biochemistry Dept, Univ of Ottawa, 40 Somerset St E, Ottawa, Ontario K1N 6N5, Canada. W298(A)

IMPERIAL COLLEGE of Science and Technology, South Kensington, SW7. Technical Staff Grade 3 vacancy in a group interested in the molecular biology of transformation by DNA tumour viruses. The work depends heavily on the techniques of genetic manipulation. Previous experience in animal cell culture and/or microbiology would be a considerable advantage. The appointment, which is supported by the cancer research campaign will be for one year in the first instance with the possibility of renewal for two further years. Salary will be within the range £3,455 to £3,860 pa (under review). Superannuation. Five weeks leave plus additional days at Christmas and Easter. Application forms can be obtained from Mr I P Blench, Department of Biochemistry, Imperial College, London SW7 2AZ or phone 589 5111 ext 1130. 2941(A)

UNIVERSITY OF HONG KONG

LECTURESHIP/ ASSISTANT LECTURESH IN PHYSIOLOGY

Applications are invited for a post Lecturer/Assistant Lecturer in Physio which has become available as a resu the institution of dental studies in University. The successful applicant wi required to participate in the teachin physiology to dental students and me students. Applicants with higher degre Physiology or medical degrees, or de degrees will be given preference.

Applicants should have some rese and teaching experience and a sp interest in one of the following ar 1. Gastro-enterological Physiolo 2. Neurophysiology, 3. Cardiovasc Physiology, 4. Reproductive Physiolo

Annual salaries (superannuable) Lecturer HK$63,540 × 4,260 — 72,060 76,320 × 4,260 — 106,140; Assis Lecturer HK$46,260 × 4,320 — 59, (£1 = HK$11.60 approx).

Starting salary will depend qualifications and experience. A medic qualified appointee who has complete pre-registration year will be appointed Lecturer at the minimum point of the s

At current rates, salaries tax will exceed 15% of gross income. Housing rental of 7½% of salary, educa allowances, long leave and medical ben are provided.

Further particulars and applica forms may be obtained from Association of Commonwe Universities (Appts), 36 Gordon Sq London WC1H 0PF, or the Assi Secretary (Recruitment), University Hong Kong, Hong Kong.

Closing date for applications i September, 1979. 2907(

UNIVERSITY OF LIVERPOOL

DEPARTMENT OF VETERINARY PARASITOLOG

Applications are invited for the po Lecturer in the Department of Veter Parasitology. The Department is hous the School of Tropical Medicin Liverpool and is responsible for tea all aspects of Parasitology to veter undergraduates and for the organisati the post-graduate MVSc course in Ap Parasitology. Applicants must ha veterinary qualification which is regist in the United Kingdom and experien laboratory animal welfare as the succ candidate will also be Curator o Animal Unit in the Tropical School.

The initial salary will be on the £4,232 to £8,452 per annum.

Applications, together with the nan three referees, should be received not than 28th September, 1979, by Registrar, The University, PO Box Liverpool L69 3BX, from whom fu particulars may be obtained. Quot RV/742/N. 2921

UNIVERSITY OF BRISTOL

POSTDOCTORAL RESEARCH ASSISTAN

An NIH funded post for work o isolation, affinity labelling and cat mechanism of mammalian glycosida available immediately.

Applications are invited from pe holding, or expecting to hold, degrees in Biochemistry, Organ Physical Chemistry, or Biol Applicants should send their curric vitae and the names of two refere Dr M L Sinnott, School of Chem University of Bristol, Cantock's C Bristol BS8 1TS. 2888

UNIVERSITY
OF BRISTOL

SCHOOL OF CHEMISTRY

POSTDOCTORAL
RESEARCH ASSISTANT

ıplications are invited for this post in the partment of Organic Chemistry, to ry out work on the structures, origins d significance of alkyl porphyrin ments in sedimentary organic matter d petroleums. This work is part of a der study directed towards derstanding the sedimentary fate or orophylls. Instrumentation includes LC, mass spectrometry (EI and CI), urier Transform 1H and 13C NMR, illary GLC and computerised GC-MS. vious experience of the chemistry of rphyrins, chlorophylls or related npounds, or of natural product mistry would be advantageous, though essential.

The appointment, funded by the SRC is one year in the first instance, at a ting salary within the range £4,232 to 776 pa (scale subject to revision with ect from 1st October, 1979).

Please send applications, with details the names of two referees, to Professor Eglinton, FRS, Organic Geochemistry it, School of Chemistry, University of stol, Cantock's Close, Bristol BS8 1TS. 2897(A)

UNIVERSITY
COLLEGE, CARDIFF

e Technical establishment of the partment includes 5 T6 members in ırge of the general laboratories, animal use, mechanical and electrical rkshops plus 12 lower grade staff. There 15 academic staff and research fellows h several research students. The partment extends over 10 floors. Salary ge: Tech 8c £5,172 to £5,625 pa (under iew). Duties to commence as soon as ssible.

Applicants, who should hold qualifi-ions of HNC level or equivalent and e extensive experience of working in ical or pre-clinical laboratories, are uested to submit a curriculum vitae ing full details and the names and dresses of two referees to the Vice-ncipal (Administration) and Registrar, iversity College, PO Box 78, Cardiff 1 1XL. Particulars of duties and terms employment will be sent to short-listed ndidates. Closing date 31st August, 9. Reference 1884. 2924(A)

UNIVERSITY
OF OXFORD

DYSON PERRINS
(ORGANIC CHEMISTRY)
LABORATORY

POSTDOCTORAL
RESEARCH ASSISTANT

postdoctoral Assistant is required to join group engaged in the synthesis of logically active peptides. Experience is sirable but not essential. The pointment, which is for one year, ewable for a second year, will start as n as possible. Salary (Grade 1A) in the ge £4,776 to £5,850 (under review) ording to age and experience, plus erannuation.

Applications, with curriculum vitae and names of two referees, should be sent as n as possible to Dr G T Young, The son Perrins Laboratory, South Parks ad, Oxford OX1 3QY. 2944(A)

ASSISTANT MICROBIOLOGIST OR CHEMIST
(Post 6S016)

Due to the current reorganisation of the Authority, a vacancy exists for an Assistant Microbiologist or Chemist in the new Gwynedd Division.

The post is to undertake analytical work on raw water, treated water, sewage and effluents in a Process Control Laboratory at Caernarfon. Though experience would be an advantage, applications from recent graduates in microbiology or chemistry interested in a career in the Water Industry will be considered.

The current salary is Grade 4 £4,179 to £4,476 *or* Grade 5 £4,635 to £4,962 with a pay award pending.

The Terms and Conditions of employment are as laid down by the National Joint Council for Water Service Staffs.

Assistance with relocation will be given where appropriate.

Closing date: 3rd September, 1979.

Application forms available from:

Personnel Officer, Gwynedd Division,
Welsh Water Authority, Bron Castell,
High Street, BANGOR, Gwynedd.
Telephone: Bangor (0248) 52881.

WELSH WATER AUTHORITY
AWDURDOD DWR CYMRU

UNIVERSITY
OF EDINBURGH

DEPARTMENT OF CHEMISTRY

POSTDOCTORAL
RESEARCH FELLOW

This SRC financed post is available in the molecular beam group investigating inelastic scattering at super-thermal energies. The work involves on-line data processing and machine control, potential surface modelling and trajectory calculations. A background in molecular scattering, computing or spectroscopy would be an advantage.

The appointment is for three years starting at point 3 on the 1A salary scale.

Applications, enclosing a curriculum vitae and the names of two referees, should be sent to Dr M A D Fluendy, Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh 9. Please quote reference 5047. 2922(A)

THE UNIVERSITY
OF MELBOURNE

CHAIR OF VETERINARY
BIOLOGY

Applications are invited for appointment to the Chair of Veterinary Biology. The Chair has been established to give academic leadership in the Department of Veterinary Preclinical Sciences and the University will consider applications from persons appropriately qualified in Veterinary Anatomy, Physiology or Pharmacology.

Salary $A34,119 per annum.

Further information, including details of application procedure, superannuation, travel and removal expenses, housing assistance, and conditions of appointment is available from the Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF.

Applications close on 26 October, 1979. 2892(A)

FACULTY POSITION IN PHYSIOLOGY

The Department of Physiological Sciences in the School of Veterinary Medicine at the University of California at Davis, invites applications from qualified individuals for a position in Ruminant Physiology. Appointment level depends on qualifications (Assistant Professor preferred). Qualifications: PhD degree in physiology or related field. A veterinary degree strongly preferred. Competence and advanced training in ruminant physiology. The candidates must have demonstrated interest, aptitude and experience in classroom teaching and demonstrated interest and achievement in research.

Teaching: Professional — lecture and laboratory instruction in the area of ruminant physiology. Lecture and laboratory instruction in other fields of systemic physiology in accordance with departmental teaching responsibilities in the professional curriculum. Graduate — Opportunity to instruct graduate students in formal courses and/or individual study in the area of the candidate's interest and competence.

Research: The development of a creative productive research program in the field of ruminant physiology is a fundamental and indispensable requirement of the position. Send curriculum vitae, a list of publications and names of three referees to:

Dr. J. R. Gillespie, Search Committee Chair, Department of Physiological Sciences, School of Veterinary Medicine, University of California, Davis, CA 95616. This position will remain open until filled. University of California is an Equal Opportunity/Affirmative Action Employer.

PERGAMON PRESS
offer the following

HIGHLY-PAID
VACANCIES

(full or part-time)

Trainee Journal Production Editors

If you have just finished your science A-levels and are looking for a career in international scientific publishing, why not apply to Pergamon who currently have a number of vacancies as trainee Journal Production Editors.
Salary on NUJ scale commencing at £2700 with the opportunity of earning £4000 after 1 year's experience.

Copy Editors

Experienced Copy and Style Editors, who would be able, either full or part time, in Oxford or in their own home, to prepare book manuscripts for typesetting. These tasks are particularly suited to men or women who have done, or are doing similar work in printing or publishing houses or Learned Societies

Re-writers

Professionally qualified people (in all subject areas) able to undertake the re-writing of original authors manuscripts to ensure linguistic accuracy and clarity of expression.

Indexers

Capable of preparing Indexes from book proofs, covering the fields of Science, Engineering, Medical, Education and Humanities.

Copy Typists

Experienced and accurate typists to operate IBM or other electric typewriters either at Pergamon or working in their own home. Pergamon also need experienced operators for Compugraphic Typesetting machines, setting both book and journal manuscripts. Either full or part-time staff will be considered.
Full-time salary, for copy typists in the range of £2700-£3500 +

PLEASANT WORKING ENVIRONMENT, SUBSIDIZED STAFF RESTAURANT, FREE PARKING AND VALUABLE PROFIT SHARING BONUS SCHEME PAID EVERY SIX MONTHS.

Should you be interested in any of these vacancies please write or telephone in confidence to:

The Publisher,
Pergamon Press Limited
Headington Hill Hall
OXFORD
OX3 0BW Oxford 64881 ext: 279

2919(A)

ELECTRON MICROSCOPY TECHNICIAN

The National Institute for Biological Standards and Control is an independant multi-disciplinary establishment concerned with testing and control of biological products used in medicine. A technician is required to assist in the development of electron microscopical methods for standardisation and control of virus vaccines and cell cultures and will be expected to undertake some routine photographic work.

Applicants should have experience in thin sectioning techniques, and some knowledge of scanning electron microscopy would be an advantage. Applicants should have HNC, HND or a suitable degree.

Further details and application forms are available from the Personnel Officer, National Institute for Biological Standards and Control, Holly Hill, Hampstead, London NW3. Telephone 01-435 2232 Extension 200, quoting reference VP/109.

POSTDOCTORAL RESEARCH ASSISTANT

Bio-physical chemist required to join research group working on membrane structure and function. Experience of surface techniques or material science would be a particular advantage. The post is tenable for up to 3 years, supported by the Science Research Council. Initial salary within range £4,261 to £4,805 plus £502 London Allowance.

Applications, naming two referees, to the School Secretary, RFHSM, 8 Hunter Street, London WC1N 1BP, as soon as possible. 2882(A)

UNIVERSITY OF NEW BRUNSWICK

FACULTY OF FORESTRY

CHAIR IN FOREST TREE IMPROVEMENT

Through the generosity of a group of New Brunswick forest industries, funds have been provided to create and support a new Chair in Forest Tree Improvement in the Department of Forest Resources.

Applications are invited from highly qualified and experienced forest scientists. The incumbent will be expected to initiate and develop a program of teaching, research and collaboration with industry in the area of tree breeding and genetics as applied to forest tree improvement, stand improvement and long term enhancement of wood quality.

It is expected that the appointment will be made at a senior level. Appropriate technical support and facilities will be provided. The appointment will be made as soon as a suitable candidate can be located.

Applications or enquiries should be directed to:

Dr. A. J. Kayll
Chairman, Department of Forest Resources
University of New Brunswick
PO Box 4400, Fredericton,
New Brunswick E3B 5A3, Canada

[REPLY INFORMATION HERE]

302(A)

UNIVERSITY OF NEW BRUNSWICK

We have the following vacancies in our Biochemistry Section:

Experimental Officer — Physical Chemist/ Electrochemist

A graduate biochemist to play a part in the discovery of new insecticides. An understanding of neurobiology would be desirable, but practical experience in insect biochemistry is not essential. However, candidates must have considerable experience of modern biochemical techniques.
The successful applicant will join a small team composed of one PhD and one graduate, responsible for initiating research in areas of insect biochemistry that could lead to a programme of chemical synthesis or produce *in vitro* methods for detecting active chemicals. Complementary work will be concerned with evaluating the mode of action of promising new insecticides and gaining an early understanding of the factors that may contribute to the development of resistance.

Experimental Officer — Biochemist

A Physical Chemist to work on the electrochemistry and reaction kinetics of exploratory organic compounds being synthesised as potential pesticides. A knowledge of chemistry at least up to HNC level is required, and experience of polarography or related techniques is desirable but not essential. The successful candidate will work closely with organic and bio-chemists, and will be in a small team headed by a PhD physical chemist. There will be scope for initiative in developing techniques and helping to design structures with the desired electrochemical properties. Jealott's Hill is the chemical and biological research centre for the crop protection interests of ICI. It is situated in open country 30 miles west of London, between Bracknell and Maidenhead. We offer competitive salaries and fringe benefits including membership of the ICI Profit Sharing and Pension Fund. Coaches run between Jealott's Hill, Bracknell and Maidenhead.

If you are interested in this vacancy please write or telephone for an application to:

Mr S R Stephenson
ICI Plant Protection Division
Jealott's Hill Research Station
Bracknell, Berks. *Ref no 79/Biochem*

ICI Plant Protection Division

2889(A)

INSTITUT CURIE ORSAY, PARIS

POSTDOCTORAL RESEARCH FELLOWS

Applications are invited for two positions as postdoctoral research fellows to work with Dr E De Maeyer on aspects of the REGULATION OF INTERFERON MRNA SYNTHESIS. It is expected that the successful candidates will have experience in one or more of the following areas: animal virology, cell biology, protein biochemistry, immunology, nucleic acid isolation, molecular hybridisation, cell-free translation.
The appointments will be for two years and the starting salary will be in the range 65,000 ffr to 85,000 ffr p.a. depending on experience (9.73 ffr = £1.00 sterling). Knowledge of the french language is not necessary.
Applications, including curriculum vitae and the names and addresses of two referees should be sent as soon as possible to:

Dr E De Maeyer,
Section De Biologie, Laboratoires 110-111-112,
Institut Curie, Université de Paris Sud,
Campus d'Orsay, 91405 Orsay, Paris, France.

university college of swansea

SENIOR RESEARCH ASSISTANTS/ RESEARCH ASSISTANT

Applications are invited for two posts of Senior Research Assistant and one post of Research Assistant in the Department of Chemistry, all supported by the Science Research Council.

Senior Research Assistant in Organic Chemistry. Applicants should have a PhD, or be about to submit for such a degree. The vacancy is to work with Dr K Smith on "Studies on Organoboranes".

Senior Research Assistant in Analytical Chemistry. The work will be to study the molecular origins of acoustic emissions from polymers under stress, under Dr D Betteridge. This work is interdisciplinary depending to a large extent on signal analysis, and applications from post-doctoral chemists, electrical engineers, material scientists, mathematicians and physicists will be considered.

Research Assistant in Organic Chemistry. Applicants should have a good honours degree (or equivalent) in Chemistry and be interested in synthetic organic chemistry. The successful applicant will work with Dr J S Davies on "Chiral Resins for Synthesis of Amino-acids" and will be expected to register for a higher degree.

The appointments which will be for one year in the first instance, from 1 October, 1979, with the possibility of renewal for a further year, will be on the following scales:

Senior Research Assistant: Commencing salary up to £4,910 per annum plus USS/USDPS benefits.

Research Assistant: Commencing salary up to £4,333 per annum plus USS/USDPS benefits.

Informal enquiries and names of two referees may be sent to the supervisors of the grants, but further particulars and application forms (2 copies) *must* be obtained from the Personnel Officer, University College of Swansea, Singleton Park, Swansea, SA2 8PP.

SENIOR RESEARCH ASSISTANT

Applications are invited for the vacancy of Senior Research Assistant in **Dynamical Sedimentology** in the **Department of Oceanography**. Applicants should be graduates in Oceanography, Physics or Civil Engineering and a postgraduate qualification, an MSc or PhD would be preferred. Mathematical skills and experience of the use of Computers, together with practical ability in the design and/or construction of equipment would be advantageous. The successful candidate will work on a programme determining the threshold of transport of heavy mineral particles under the combined influence of unidirectional and oscillatory flows, under the direction of Dr M. B. Collins.

The appointment will be for two years from October 1, 1979 and the commencing salary will be on a scale up to £4,910 per annum plus USS/USDPS benefits.

Informal enquiries may be made to Dr. M. B. Collins, to whom a short report or published papers exemplifying original work should be sent, together with the names and addresses of two referees, but application forms (2 copies) and further particulars *must* be obtained from the Personnel Officer, University College of Swansea, Singleton Park, Swansea, SA2 8PP. Closing date for all applications, Friday, September 7, 1979. 2927(A)

GERMAN CANCER RESEARCH CENTRE

INSTITUTE OF EXPERIMENTAL PATHOLOGY

Applications are invited for the post of a

POSTDOCTORAL RESEARCH ASSISTANT (M.D.)

to work on a project on the "Development and Application of Automated Procedures for the Early Detection of Cancer". Knowledge in Cytology would be an advantage.

The post is tenable from 1.8.1979 with an initial salary on Range IIa of the German Salary Scale (BAT).

For further details please contact German Cancer Research Center, Administration, Im Neuenheimer Feld 280, 6900 Heidelberg. W295(A)

MEDICAL RESEARCH COUNCIL
TOXICOLOGY UNIT
SCIENTIST

Scientist required to carry out research on the action of cadmium and other metals on mammalian systems. The aim will be to understand the mechanisms of the toxic action of such metals and the studies can range from a molecular to a whole animal approach.

A suitable candidate should have at least two years postdoctoral experience and will be eligible for a limited appointment for five years. Salary according to age and experience in the range of £4,776 to £6,108.

Applications should be sent to Dr W. N. Aldridge, Toxicology Unit, Woodmansterne Road, Carshalton, Surrey SM5 4EF by 15th September, 1979.

2947(A)

MRC Medical Research Council

See Page xxvi for a further APPOINTMENTS VACANT

UNIVERSITY OF NOTTINGHAM

CANCER RESEARCH CAMPAIGN LABORATORIES

Applications are invited for a post-doctoral research appointment to join a group studying the biology of chemical carcinogenesis. The project under the direction of Professor R. W. Baldwin is concerned with immunological studies in the early phases of chemical carcinogenesis and is supported by the Cancer Research Campaign.

Salary in range £4,333 to £6,644 (under review) and the starting date after September 1st by mutual agreement.

Applications in writing with full curriculum vitae and names of two academic referees to the Staff Appointments Officer, University of Nottingham, University Park, Nottingham NG7 2RD, Notts. 2883(A)

UNIVERSITY OF LEICESTER/ICI JOINT LABORATORY

RESEARCH TECHNICIANS

Two vacancies exist for suitably qualified candidates to work as technicians on projects in eukaryotic molecular genetics. The techniques to be used include mRNA isolation, copy DNA synthesis and cloning in bacteria, *in vitro* translation and nucleic acid sequencing.

Appointments will be made at Grade 3 or Grade 5 according to qualifications and experience. Salary scales (under review) are £2,931 to £3,336 for Grade 3, £3,474 to £4,056 for Grade 5.

Applications, in writing, including a detailed curriculum vitae and naming two referees, should be sent to Miss S N Dilks, Chief Technician, ICI Joint Laboratory, Adrian Building, University of Leicester, Leicester, LE1 7RH. 2936(A)

SOUTH GLAMORGAN HEALTH AUTHORITY (T)
VELINDRE HOSPITAL, CARDIFF

Graduate Research Assistant (Radiobiology)
(Scientific Officer (PTA/A)

Applications are invited for the above post in the Department of Radiobiology at Velindre Hospital. The post is funded for three years by the Welsh Scheme for Development of Health and Social Research. The successful candidate will help develop *in vitro* systems for assaying the effects of cytotoxic drugs.

Previous experience with mammalian tissue culture or organ culture, or a background in Microbiology, Biochemistry or Pharmacy will be an advantage but is not essential. The starting salary is £3,486 (under review).

For further details and a visit to the laboratories, contact: Dr. J. L. Moore or Mr. J. Court. Telephone Cardiff 63325, Ext. 32.

Application forms are obtainable from the Unit Administrator, Velindre Hospital, Whitchurch, Cardiff CF4 7XL and should be returned by 7th September, 1979.

2923(A)

MEDICAL RESEARCH COUNCIL

CYCLOTRON UNIT

A medically qualified Pulmonary Physiologist is required for a programme of research into regional lung function. The position entails being involved in the development of technique to measure regional lung function using cyclotron-produced radioisotopes and a Positron Emission Computerised Axial Tomograph. It is intended that the methods developed be used to study regional lung function in various pulmonary disorders.

The appointment will be for one year. Salary according to age and experience, in the range £5,576 to £7,129 (inclusive of London Weighting).

Please write, giving qualifications and curriculum vitae to: Miss A Pires, MRC Cyclotron Unit, Hammersmith Hospital, Ducane Road, London W12 0HS. (Tel: 01-743 4594, extn 103). 2908(A)

GRADUATE REQUIRED for Nolan Laboratories, St. Mary Abbots Hospital, Marloes Road, London W8. Duties mainly tissue typing for bone marrow transplant programme. Knowledge of immunology and experience of tissue typing an advantage. Remuneration according to age and experience. Please apply in writing to Dr Ann White, Nolan Laboratories at the above address. 2914(A)

RESEARCH IN PROTEIN METABOLISM

Applications are invited from graduates (equivalent) with relevant experience for t post of Medical Laboratory Scienti Officer/Senior MLSO to assist with project on the regulation of prote synthesis and breakdown in animal tissu carried out at the Clinical Nutrition Metabolism Unit, St Pancras Hospit The appointment will be for up to two yea on the salary scales £3,261 to £3,9 (MLSO)/£3,813 to £4,680 (Senior) (bo under review) plus £354 Lond Weighting.

Applications, consisting of f education and career details and nami two referees, should be sent to Secreta (A1), London School of Hygiene Tropical Medicine, Keppel Street, Lond WC1E 7HT.

2912(A)

COURSES

THE HATFIELD POLYTECHNIC

MSc in ASTRONOMY and ASTRONAUTICS

(part-time — two evenings per week three years).

Induction course starts 24th Septemb 1979. MSc course starts 11th Februa 1980.

For further details, telephone Hatfie 68100 Ext 324 or write to The Secreta (MSc), The Hatfield Polytechn Observatory, Bayfordbury, Hertfor Herts SG13 8LD. 2890(D)

FELLOWSHIPS

STAFF FELLOWSHIP

The Clinical Branch, National Eye Institute, offers a Staff Fellowship in the Clinical Eye Pathology Section. Applicants may be PhDs or MDs and must have between four and six years' postdoctoral experience in immunology and immunochemistry. In addition, applicants must be U.S. citizens or resident aliens who would be eligible for citizenship within four years. The initial appointment will be made for two years with possible extension. Salary ranges from $20,000 to $37,500 and would be commensurate with the level of training and experience.

Interested persons should send curriculum vitae no later than September 14, 1979 to Karen M. Wright, Deputy Personnel Officer, National Eye Institute, National Institutes of Health, Public Health Service, Bethesda, MD 20205. Phone (301) 496 4274 for further information. Equal Opportunity Employer.

NATIONAL INSTITUTES OF HEALTH

W291(E)

ELLOWSHIPS continued

RESEARCH FELLOWSHIP

Imperial Cancer Research Fund Mill Hill Laboratories London NW7 1AD

A post-doctoral Fellow is sought to oin a group working on the control of lifferentiation of stalk and spore cells n Dictyostelium discoideum. The Fellow would be expected to employ genetical and biochemical techniques o analyse the cell interactions involved n differentiation in this organism.

Appointment will be for three years. Salary with entry according to qualifications and experience within ange £5,823 to £7,129.

Further information from Dr J Gross (01 959 3236). Application with urriculum vitae and names of two eferees, should be sent to The Secretary, Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2A 3PX, by 30th September, 1979, quoting reference 345/79.

2862(E)

UNIVERSITY OF EDINBURGH

EPARTMENT OF BIOCHEMISTRY

POSTDOCTORAL RESEARCH FELLOWSHIP

plications are invited for this post to rk on the mode of action and uptake of drug Suramin in *Trypanosoma brucei* l the cause of resistance to that drug. Salary £4,333 per annum (plus eerannuation), with effect from 1st tober 1979.

The post, financed by the World Health ganisation's Special Programme for search and Training in Tropical eases, will be for one year initially with sible extension for a further two years. Applications with curriculum vitae and names of two referees should be sent to I B R Bowman, Department of chemistry, University of Edinburgh dical School, Teviot Place, Edinburgh, 8 9AG, not later than 30th August, 9. Please quote reference 5046.

2909(E)

UNIVERSITY OF GLASGOW

DEPARTMENT OF MICROBIOLOGY

POSTDOCTORAL RESEARCH FELLOWSHIP IN PROTEIN-LIPID INTERACTIONS

plications are invited for a three year C-financed post-doctoral appointment work with Dr J H Freer and Dr T H kbeck on the interaction of bacterial tolytic toxins with mixed lipid nolayers, liposomes and cell mbranes.

The appointment is for three years mmencing October 1979 (or as soon as ssible thereafter) in the salary range 1A, 333 to £7,521 (under review) plus eerannuation.

Applicants should preferably have a kground in biochemistry or chemistry h an interest in surface chemistry or terial toxins.

Applications, with the names of two erees, should be submitted to Dr J H er, Department of Microbiology, iversity of Glasgow, The Alexander ne Building, Garscube Estate, arsden, Glasgow G61 1QH from whom ther particulars may be obtained. In ly please quote Ref No. 4500M.

2931(E)

RESEARCH FELLOWSHIPS

at Continental Universities

Applications are invited for awards by the CIBA-GEIGY Fellowship Trust for the academic year 1980-81.

Senior CIBA-GEIGY Fellowships

Senior CIBA-GEIGY Fellowships will be awarded to start from an agreed date during the academic year 1980/81. These will be available normally to lecturers, senior lecturers, readers or those who have held comparable permanent teaching positions for a period of at least five years in the field of chemistry, biochemistry, chemical technology (including chemical engineering) and biology, particularly in its relation to chemistry, at United Kingdom or Republic of Ireland universities, polytechnics, or comparable teaching institutions, who wish to undertake special study at an agreed continental European university or technological university.

Duration of the award: minimum period of six months and up to two years.

Value of the award: £8,000 per annum plus travelling expenses. CIBA-GEIGY Fellowship awards are intended to supplement Fellows' salaries for the period of tenure.

No CIBA-GEIGY Fellowships for graduates will be made for the academic year 1980-81.

Further details and application forms, which should be submitted before 1 November 1979, can be obtained from The Secretary, The CIBA-GEIGY Fellowship Trust, 30 Buckingham Gate, London SW1E 6LH (Telephone: 01-828 5676).

CIBA–GEIGY

2898(E)

POST DOCTORAL RESEARCH FELLOWSHIPS

Applications are invited from organic or polymer chemists for two SRC Post-doctoral Fellowships to work in collaboration with Dr. P. Hodge. The topics are "Asymmetric syntheses using chiral polymer-supported catalysts or reagents" and "Kinetic studies of some polymer-supported reactions".

The appointments will be for one year in the first instance renewable for a second year. Commencing date 1st October 1979 or as soon as possible thereafter. Initial salaries £4,910 p.a. plus USS Benefits.

Applications, giving the names of two referees, should be made to Dr. P. Hodge, Chemistry Department, University of Lancaster, Bailrigg, Lancaster LA1 4YA.

STUDENTSHIPS

UNIVERSITY OF OTTAWA

DEPARTMENT OF BIOCHEMISTRY

PLANT PROTEIN UTILIZATION

Applications are invited from graduates in chemistry, biology, or biochemistry to work on several projects investigating (a) protein-phenol interactions in oilseeds (b) lipolytic enzymes in high-protein oats (c) oat storage proteins (d) microchemical localization of phytate, glucosinolates, protein, etc. in rapeseed (e) Fraction-1 protein from hybrid poplar foliage. Research in the department's Nutrition Program is in collaboration with the food industry, the Food Research Institute of Agriculture Canada and the Ontario Ministry of Natural Resources. Graduate Research Scholarships ($6,500) are available.

Additional financial assistance is available from research stipends and demonstratorships (up to $2,000).

Please apply to Dr I Altosaar, Biochem Dept, Univ of Ottawa, 40 Somerset St E, Ottawa, Ontario K1N 6N5 Canada.

W299(F)

ASSISTANTSHIPS

UNIVERISITY
OF BRISTOL

Post-Doctoral Research in Theoretical Chemistry

Applications are invited for an SRC funded post-doctoral research assistantship to study the theory of photodissociation processes of small molecules. These processes are being studied in sophisticated experiments and the present work is aimed at using theoretical methods to predict the outcome of such experiments and to provide a better understanding of the photodissociation process itself.'

Applicants should send a curriculum vitae and the names of two referees to Dr G G Balint-Kurti, School of Chemistry, University of Bristol, Bristol BS8 1TS.

2887(P)

UNIVERSITY
OF DURHAM
DEPARTMENT OF BOTANY

Applications are invited for a

POSTDOCTORAL
SENIOR RESEARCH
ASSISTANTSHIP

tenable for one or two years from 1 September, 1979 or as soon as possible thereafter in the Glycoprotein Research Unit under the direction of Dr P W Kent. Preference will be given to candidates with experience of cell culture techniques. Initial salary in range £4,232 to £5,048 pa (£4,333 to £5,199 pa from 1 October) plus superannuation.

Applications (3 copies) naming three referees should be sent by 31 August, 1979 to the Registrar and Secretary, Science Laboratories, South Road, Durham, DH1 3LE, from whom further particulars may be obtained. 2884(P)

CONFERENCES

A TWO-DAY CONFERENCE

Advances in Microbiological Techniques, Foods, Pharmaceuticals and Cosmetics

To be held at the:

Sudbury Conference Centre, London EC1

Tuesday 25th September, 1979

Plenary Lecture: Microbiological techniques in the 1980's *Professor G W Gould,* Unilever Research, Sharnbrook, Beds.

Survey of methods for the identification of medically important micro-organisms *Dr Elizabeth J Shaw,* St Bartholomew's Hospital, London.

The enumeration of micro-organisms in cosmetic products *Professor H Beerens, Ch Romond and C Lepage,* Universite du Droit et de la Sante, Lille, France.

Bioassay and enumeration by flow microcalorimetry *Dr A E Beezer,* Chelsea College, London.

The enumeration of micro-organisms using the spiral plate maker *V Lach,* Public Health Laboratory Service Centre for Applied Microbiological Research, Porton, Wilts.

Optical microscopy in microbiology *Dr K T Holland,* The University of Leeds, Leeds.

Enumeration of micro-organisms using bioluminescence techniques *Dr H H Johnston,* The Radcliffe Infirmary, Oxford.

The fluorescent labelled antibody technique *Irene Batty,* The Wellcome Research Laboratories, Beckenham, Kent.

Wednesday 26th September, 1979

Identification of micro-organisms by measurement of enzyme activity *Dr S Bascome,* St Mary's Hospital Medical School, London.

Kits for the identification of micro-organisms *Maggie Duke,* Elizabeth Arden Ltd., London.

The use of chromatography in food microbiology *M Ackland,* Metal Box Ltd., London

Computer-based bacterial identification systems *M Stevens,* University of Leicester Medical School, Leicester.

The uses of microbiological standards for foods *Dr R H G Charles,* Department of Health and Social Security, London.

Pharmacopeial and regulatory body standards for sterilization and preservation *Dr H S Bean,* Chelsea College, London.

European microbiological cosmetic standards *P E Harbord,* Johnson & Johnson Ltd., Portsmouth, Hants.

Concluding remarks *Professor D A A Mossel,* University of Utrecht, Holland.

For registration forms contact
Beverly Humphrey, Scientific Symposia Ltd., 33/35 Bowling Green Lane, London EC1R 0DA.

Please send me further details on the conference *ADVANCES IN MICROBIOLOGICAL TECHNIQUES, FOODS, PHARMACEUTICALS AND COSMETICS*

GRANTS and SCHOLARSHIPS

EUROPEAN SCIENCE FOUNDATION

EUROPEAN TRAINING PROGRAMME IN BRAIN AND BEHAVIOUR RESEARCH

TWINNING GRANTS

ETP twinning grants are aimed at the promotion of contacts and collaboration between European institutes working in the field of brain and behaviour. Proposals can be submitted by 2 or 3 European laboratories, which should be located in different countries and be either working in the same field of research or in different disciplines which complement each other. Applicants should be submitted by only one of the participating institutes and be accompanied by (a) letter(s) of concurrence from the other(s).

Twinning grants are not paid in advance. Instead, credits of up to Ff10,000 are granted for projects selected by the International Scientific Committee. The costs incurred during the reciprocal visits of the teams involved are reimbursed upon termination of the project within the limits of the original grant.

The deadlines for completed applications is *15th March and 15th September.* Further information and application forms may be obtained from:

Dr. Stephanie ZOBRIST

NICKTRANSLATIONSYSTEM

The world's first. Packaged complete.

Naturally it is more convenient than assembling the components yourself. But even more important is its reliability.

For example, the *E.coli* DNA Polymerase I is cloned in our laboratories to ensure extremely high reproducibility. The dCTP, [α-^{32}P]- is tested for nick translation by our Biological Testing Laboratory. (Typical incorporation is 40%, and we guarantee 1 x 10^8 dpm/μg DNA.) The supercoil PBR322 Plasmid DNA control we use to test each lot of systems is included so you can check yours. Finally, the DNAse I, dNTP mixture, stop-buffer, and sterile deionized water are optimized for compatibility and stability. Approximately twenty assays can be run.

A bulletin describing this exclusive system is yours for the asking.

LIQUID SCINTILLATION CHEMICALS

We're at Your Service More Than Ever Before.

Our sales, service, and technical assistance have never been stronger in Europe. As a result you can expect immediate response from the NEN office in your country, and fast delivery of the products you need from the world's most widely referenced selection of liquid scintillation chemicals.

If you need technical assistance, you will find that our people are exceptionally well equipped to provide it. But if they don't have the answer, the director of our LSC Applications Laboratory, Dr. Yutaka Kobayashi, will help you.

In short, we're doing everything to meet the rapidly increasing demand for NEN liquid scintillation chemicals in Europe—with an expanded technical sales force, locally available products, and fast response to technical questions.

We look forward to your call.

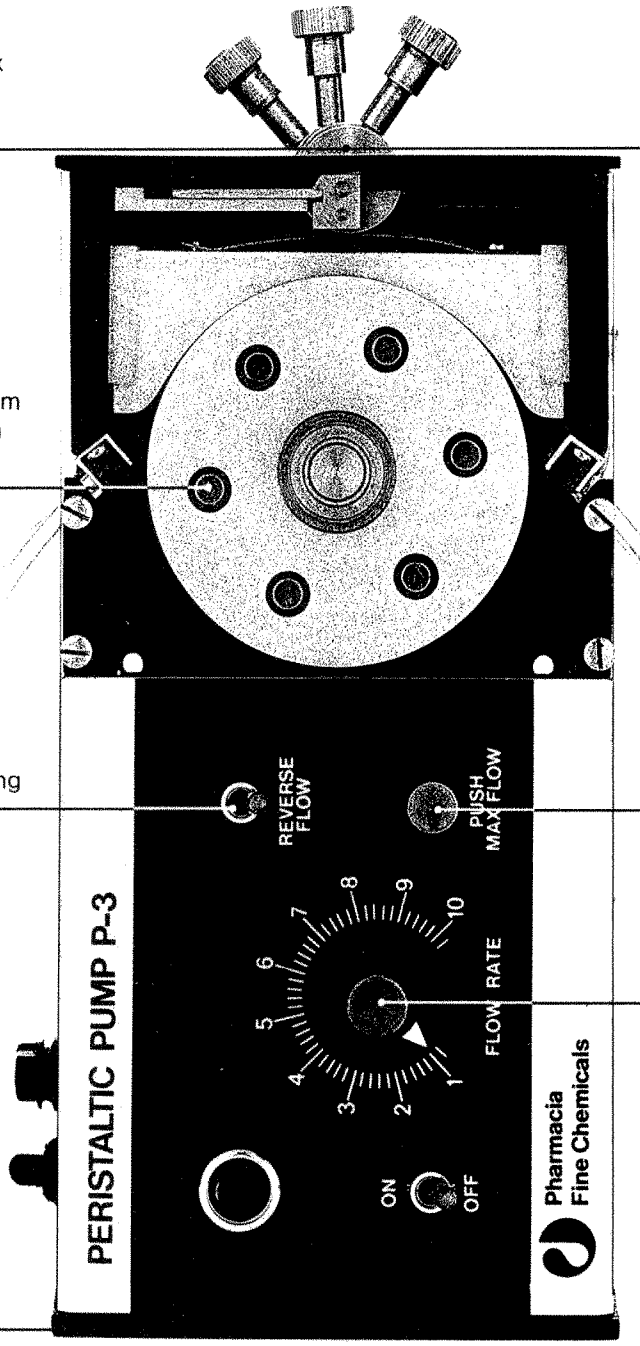
The Pump
Check what it can do for you!

Linear, concave or convex gradient formation by three channels

Different flow rates to three columns by three channels

Undisturbed chromatogram due to minimum pulsation by six gear driven rollers



Flow versatility with three different tube sizes

Saves time when clearing bubbles from system by overriding pre-set flow rate

Can save column repacking

Reliable flow rate (0.6—400 ml/hr) due to electronic load and temperature compensation

Saves bench space. Only 11 x 11 cm

The Pharmacia Peristaltic Pump P-3 is your ideal general-purpose laboratory pump for column chromatography, density gradient formation and many other biochemical techniques where reliable liquid flows are required.

Its versatility gives you convenience and saves your time and money. Let this pump work for you in your lab. Ask for detailed information today.

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (*a*) is preferred to e^a if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unaltered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**,1 (1975) and **264**, v, 11 Nov. (1976).

UK's wasted opportunity at UNCSTD

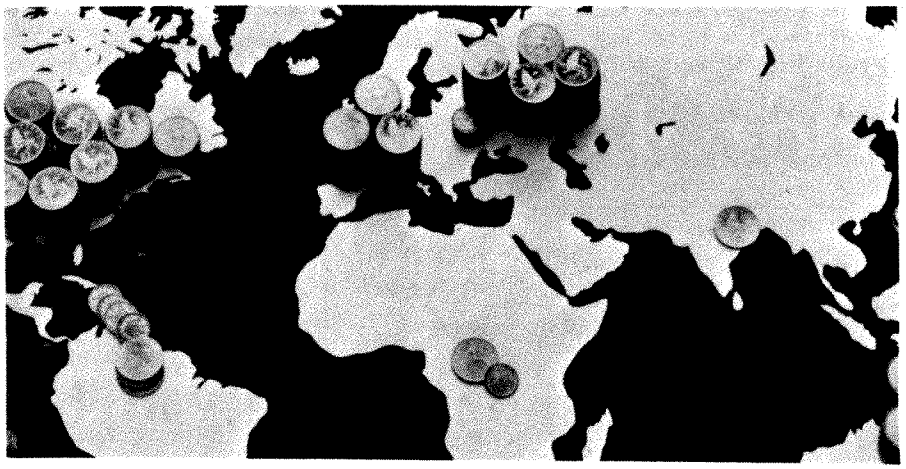
Whatever may or may not be decided at UNCSTD in Vienna these two weeks, it is perfectly clear that the world scientific and technological community is experiencing strong pressures for change, for instance through proposals for the establishment of a massive global research and development fund, and through demands that the legal framework for the transfer of technology be restructured. It is thus vitally important that all those who attend UNCSTD take back to their home country a clear impression of the forces at work and alert their colleagues in every possible way to the need for new thinking. To a degree press reports help, but a very important ingredient is what individual people who attend do.

The constitution of the British delegation to UNCSTD is — for whatever reason — such as to make this job very difficult to perform for the scientific and technological community. A delegation of twenty or so could have included some well connected scientists, some influential industrialists, some representatives of education, and some non-governmental development experts in addition to the necessary complement of civil servants. Instead the delegation comprises a minister (for two days), eight civil servants, five representatives of the Vienna embassy, three private or personal secretaries and only two people who could in any sense be regarded as outsiders. The burden on these two to inform the broadest community is intolerable. It will be interesting to see what help they get from their civil-servant colleagues in the months ahead.

Science, nonsense and responsibility

THE right — and responsibility — of the layman to exert an influence on the actions of scientists and technologists is becoming firmly established, as is evidenced this week by the controversy over the exclusion of journalists from an international meeting on short-term testing for carcinogens (see p.623). But is there not an equal right and responsibility for the scientist to guide the layman? Guidance is surely needed. The misuse of science by those often lacking in scientific training and understanding, but never lacking either conviction or commercial acumen, is now commonplace. It is commonplace because there are profits to be made from it.

For example, it is there even in the bookshops. A new form of escapism has been packaged as an alternative to science fiction, romantic fiction and thrillers. The new genre treats as fact a wide range of spurious topics. Themes include the artefacts left by our extragalactic forefathers, the possibility of disappearing through triangular holes in the sky over the Caribbean, the everyday lives of UFO-flying folk, paranormal fork-bending and outrageous claims about the influence that this additive-free food or that celestial body might have on our lives. A factor common to all these books, it seems, is the need for belief. A recent example of the extent to which strongly held but totally unfounded belief can resist the weight of fact is the saga of the alleged anti-cancer drug laetrile.



Can this need for belief be satisfied by something more sober than UFOs and cancer cures? By, say, a belief that an analytical and scientific approach to a physical problem will lead to as near as we can get to a solution? This will be possible only if genuine critical science, with its clarities *and* uncertainties, is sold to the public with the determination that sells pseudo-science. It does not help to hold closed meetings and so increase the public's natural distrust of 'the expert'. The exercise is difficult, but it must be undertaken, or the voice of reason will not be heard at all.

True science does answer back sometimes. The BBC *Horizon* series carried an excellent critique of von Daniken's books. But many thousands more of his books will have been sold since then. Science should answer back more loudly and more often. One medium which invites such a response is the relatively new one (in the UK) of local radio, which thrives on the cheap-to-run 'phone-in' programme. In these programmes all forms of fringe and suspect forms of pseudo-science are often discussed by 'experts', and the more far-fetched the thesis proposed the more enthusiastic the response from the listeners. Just as harmful are 'open-line' programmes in which callers attempt to discuss subjects which neither the caller nor the programme presenter comprehends. Presenters are generally conscientious and, especially on medical matters, make pleas for calls from more qualified listeners. The pleas are often unanswered. This seems a pity because, although discussion of this type are certain to be shallow and are often not conducted very well, a shallow discussion with some sense in it must be better than one with no sense.

It may be true that 'truth will out', as it did eventually for laetrile. But scientific truth will 'out' much faster if it is sold with more enthusiasm, and if this means descending to the level of the market place, then perhaps that's as it should be.

The poor meet the rich

'Nature' correspondents report from Vienna on the opening sessions of the United Nations Conference on Science and Technology for Development

Third World: we will negotiate

DELEGATES to UNCSTD from a wide range of Third World countries agreed at a meeting in Bucharest last week that, at least at the start of the conference, they will bury economic and ideological differences behind a common negotiating strategy. They also agreed to stand firm behind the developing countries' proposals for a draft plan of action to emerge from UNCSTD — although they are prepared to negotiate on the plan's main demands rather than invite confrontation by sticking to a hard line.

The meeting was organised by the Group of 77 which has been negotiating on behalf of over 120 developing countries during the UNCSTD preparatory meetings. Representatives from the developed countries were relieved to hear that the Group of 77 would not seek initial confrontation. Although the developed countries are not prepared to accept all the demands that the developing countries have included in the proposed plan of action, they are keen, for political and economic reasons, to engineer a successful outcome to the conference.

Before the Bucharest meeting, some developing countries had complained that the proposed draft plan did not reflect their particular concerns. (The draft is the basis for the negotiations currently taking place in Vienna). Some African countries, for example, had complained that the proposals were too heavily weighted towards measures to benefit the more advanced of the Group of 77 countries — for example, with conditions governing technology transfer — and would not do enough to meet the technical needs of the poorest countries.

The Bucharest meeting agreed to recommend that the plenary session in Vienna establish a special working group to look at proposals for areas in which greater scientific and technical effort should be focused. In return the African groups agreed to support the Group of 77's proposals for a new funding system and new institutional arrangements for science and technology with the UN. Both proposals will be examined by UNCSTD's two main committees.

Members of the Group of 77 still differ, however, over how the new institutional arrangements would operate to assure the politically weaker countries adequate control over research funds and their application.

A statement summarising the demands of the plan of action was issued at the end of the meeting. It says that inequalities in all fields of international economic relations are especially actue in science and technology. Despite the efforts of the developing nations there has been no real progress towards setting up a New International Economic Order with science and technology forming an intergral part. The statement expresses alarm at the large fraction of global research expenditure devoted to defence and asks for "free and full access to scientific and technical knowledge, discoveries and innovations".

International cooperation should also play an important part in harnessing science and technology to the social objectives of the developing countries, the statement says. "For this, global and fundamental structural changes are required in the existing distribution of scientific and technological capacities in the world, in order to ensure increased participation by the developing countries in the quest for new scientific and technological knowledge".

In line with the suggested plan of action, the statement urges that international law governing technology transfer should be "restructured" in line with the goals of the developing countries who should be able to participate in financing mechanisms set up for scientific and technological development. The statement also urges support for measures to increase scientific and technical cooperation between developing countries. It says that practical measures "should be undertaken to support the cause of national liberation of peoples and territories under foreign occupation, control and domination, racism and racial discrimination, to enable them also to benefit from the application of science and technology for their development".

Arab group expel Egypt and establish Libya as spokesman

The decisions taken at the Tenth Conference of Islamic Foreign Ministers, held in Fez during April, are now being implemented by a strong 'Arab group' that has emerged at UNCSTD. The Islamic conference decided to boycott Egypt on all issues and support the Palestine Liberation Organisation.

In the past Egypt has assumed a natural leadership on Arab issues, in the field of science and technology, and this is the first time it has faced a determined and joint opposition to its efforts to lead the Arab group. Libya was unanimously elected to lead the group last week-end despite the fact that, nominated as a vice-president for North Africa, it was absent from its first meeting.

Alienation of Egypt from the Arab group has provided even stronger Arab support for the PLO delegation to UNCSTD. "We are determined to get a nation-state status for the PLO" a member of the Syrian delegation declared. At their first meeting, the group decided not to articulate an OPEC (or more appropriately, AOPEC) position. OPEC Arab countries will play a low-key role where we are allowed to do so" and will merge their identities within the Arab group.

The group also decided to give full support to the announced position of the Group of 77. Although the stance taken by the Group of 77 is a little too radical for some of the more conservative Arab states, like Saudi Arabia, Kuwait and the UAE, these states have been pursuaded to support the Group of 77 as much as possible. Similarly Syria, which has shown considerable opposition to some declarations of the Group of 77, has decided to overlook its objections and support the decisions of the Arab group. Dr Shakir Fahm, Syrian Minister of Higher Education and leader of the Syrian delegation to UNCSTD says, "now is the time for the developing countries to show

their strength. This strength lies in unity".

What the Arab group did not discuss is the financing of a development fund to help scientific and technological activities in the developing countries. Whether Saudi Arabia and other oil-rich Arab states will back such a fund to the tune of $65 million a year for the first two years of the fund, as some suggested, they did not decide — though there is some indication that Saudi Arabia will give in to the US pressure. The Saudi aid to developing countries granted through the Saudi Development Fund, far exceeds this sum in an average year. The Saudi decision to support the fund, if it is forthcoming, will therefore be in line with their aid policies.

In addition to national efforts in such countries, international cooperation can and should play an important part, the statement says. "For this global and fundamental structural changes are required in the existing distribution of scientific and technological capacities in the world, in order to ensure increase participation by the developing countries in the quest for scientific and technological knowledge."

Ziauddin Sardar

'In everyone's interest' to transfer technology

The transfer of technology is not an issue of necessary conflict between developed and the developing countries, according to Crown Prince Hassan of Jordan, who shoulders the responsibility for social and economic planning in Jordan. Speaking during the general debate of the second plenary meeting at UNCSTD, Prince Hassan said that "despite short term disagreements and apparent disparities, in the long term, technology transfer is in everybody's interest". He warned, however, that technology "is not a commodity which can be copied to exaction. The transferred technology has to be appropriate to the needs of the receipient country".

Many developing countries, said the Prince, lack the basic conditions for the establishment of agencies that promote and enhance technology. Furthermore, technology in the developed countries is based on a particular concept of entrepreneurship — that motivated by economic and commercial considerations. The Prince questioned the desirability of the developing countries adopting such a concept and argued for a "spirit of resourcefulness" or "appropriate entrepreneurship".

The Prince pointed out that at present much aid is channeled towards the poorest members of the Third World, the decisions for granting aid being made on the basis of gross national product (GNP). But there is hardly any relationship, argued the prince, between GNP per capita and the levels of development.

Talking of the brain drain, the Prince emphasised that the human dimensions of the problem, "which have a direct bearing on technological and scientific development in both labour-exporting and labour-importing countries", are often overlooked.

Crown Prince Hassan suggested that the labour exporting countries should turn the situation to their advantage through policies that aim to utilise the experience of their nationals working abroad. "These should take the form of annual feedback programmes, where highly trained scientists and technologists working abroad would come back to their countries for varying lengths of time".

Making an obvious reference to the proposed global development fund, the prince said that "we have to be careful before we decide to create yet another international agency providing yet another variation on the existing manner of solving an already identified problem".

Ziauddin Sardar

Waldheim attacks 'wasteful consumerism'

A major task of UNCSTD is to help generate universal acceptance of the need to direct the use of humanity's scientific and technological potential to constructive ends, Dr Kurt Waldheim, Secretary General of the United Nations, told the opening session of the conference on Monday morning.

In a speech which reflected many of the ideas put forward by the conference secretariat during the preparatory process, Dr Kurt Waldheim singled out three areas in which he claimed much of human ingenuity and innovative ability had been misdirected into areas not beneficial for mankind: military technology; a type of economic growth which ignored damage to the environment or the social and cultural fabric; and the support of "wasteful consumerism in a world where famine and malnutrition are tragically present".

Another motivating factor behind the conference was the enormous imbalance in research and development being undertaken internationally, he said, resulting in developing countries having to depend excessively on imported technology. This hampered the growth of indigenous skills more harmonious with local conditions and socials or economic needs.

"This becomes a self-generating process and breeds over-all dependence. The starting point for breaking this circle is to enable the developing countries to gather and share the scientific knowledge so as to enhance their technological capabilities and accelerate their development", he said.

Three elements were crucial in designing a successful programme of action: a conscious political will, increased funding for science and technology at the national and international levels, and the institution of an efficient mechanism for this purpose. Finally, directly echoing words used on many occasions by conference Secretary-General Mr Frank da Costa, Dr Waldheim said that the real divisions in the world were not between the north and south or east and west, but between those in favour of a passive continuation of the status quo, "which is prejudicial to all" and those in favour of dynamism, changes and innovation. "Let this conference signal the fact that science and technology can unite the developed and the developing countries in the common cause of the world's future as a whole", Dr Waldheim said. □

Britain opposes creation of new mechanisms

A greater proportion of national and international aid budgets should be devoted to scientific and technological aspects of development, but there is no need at present for new financing mechanisms or institutional arrangements to do this. Such was the main message of the British delegation's contribution to the UNCSTD plenary debate on Wednesday morning.

Mr Neil Marten, UK Minister for Overseas Development, told the assembled delegates that, if developing countries so wished, Britain would be prepared to devote an increasing share of its bilateral aid programme to scientific and technological activities in the Third World. He also announced that Britain is considering plans to set up a technology transfer centre to act as a general switch-

©Macmillan Journals Ltd 1979

board for enquries about British technology.

However on the two main issues which are likely to dominate negotiations during UNCSTD — the Group of 77's proposal for a new international financing system for science and technology, and for a new co-ordinating body within the UN — the British response was lukewarm at best, reflecting the position of other EEC countries.

Nor did the British show any keenness to discuss the heated topic of technology transfer or the conduct of multinational companies, and area where encouragement and support of existing channels and procedures is preferred to greater regulation and control.

"Experience shows the advisabilty of making progress through continuing change based on tested practices and procedures, rather than embarking on abrupt changes of direction. We have serious doubts about the value of any new financial mechanisms or the separation of funds for science and technology for development", Mr Marten said.

"Given that aid budgets are limited, the separation of funds is likely to drain off the resources available for development into different pockets. This would make it difficult for individual recipient governments to set their own priorities clearly and would lead to inflexible and inefficient programmes." □

Danes urge the need for compromise

In one of the most direct statements made on the opening afternoon of the conference, the head of the Danish delegation said that it was "imperative" that a compromise be reached on various proposals for financial resources to support greater scientific and technological efforts in developing countries, if the conference was to be made a success.

"My country is definitely prepared to carry its fair and proportionate share of the financing of science and technology" the Danish representative, Mme Lise Ostergaard told the conference, an indirect reference to proposals for a new fund largely financed by the developed countries.

● A further pledge for additional financial support came from the Swedish delegation. Pointing out that Sweden is already one of the few countries which contributes more than the 0.7% of its gross national product to international development previously agreed as a global target, the head of the Swedish delegation said that agreement had already been reached on a number of recommendations which, for their implementation, demanded increased financial resources.

Sweden was prepared "together with other countries and on the basis of a fair burden-sharing formula, to make a substantial increase of our contributions in support of international cooperation in the field of science and technology.

US supports 'reasonable ventures'

Speaking on the opening afternoon of UNCSTD, the chairman of the US delegation announced that the US was prepared to join "reasonable ventures" to strengthen worldwide scientific and technological cooperation.

This theme was echoed in a message from President Carter to the conference, in which he said that the US was willing to support "all practical endeavours" to help overcome problems such as food scarcity, the energy crisis, and the population explosion.

Although no direct comment was made in either pronouncement, the choice of words was partly a response to some of the proposals contained in the draft plan of action submitted to the conference by the Group of 77 — such as the setting up of a new international financing mechanism totalling $2 billion by 1985 and $2 billion by 1990 — which has previously been characterised by US negotiators as being "unrealistic".

US officials have not made it clear what they would support as a more "practical" alternative. However they indicate that the executive branch would be prepared to look favourably in the order of $1.50 million over the next two years, although pointing out that no firm commitment to such a contribution can be made without the support of Congress.

In his speech to the conference plenary session, Father Theodore Hesburg, president of Notre Dame Univeristy and chairman of the US delegation, said that the global economy was not working as well as it should for either the poor or the rich countries, and that the patters of worldwide technology generation, diffusion and utilisation lacked the cohesion that would incorporate and benefit the majority of people. "We have not yet found the right mix between scientific excellence and needed technologies" he said.

It was an imperfect global economic order that did not fully benefit from the "robust and dynamic role" of international business and industry, and had not yet found "the right balance between the interests of private enterprise and of the developing countries" he said — an implicit recognition of the need to negotiate on issues such as the conditions for the international transfer of technology.

"The task of this conference is not one of restating the errors of the past but of weaving science and technology into the fabric of the future, the fabric of development. We need collaboration, not confrontation", Father Hessburgh said.

Among the specific proposals were that the US would take the initiative to bring together the operators of remote sensing satellites as systems. In addition, it was necessary for developing countries to have access to the leverage provided by scientific and technological information, if more just and equitable patterns of scientific and technological cooperation were to be achieved.

Referring to President Carter's description of science and technology for development as a "joint venture", Father Hessburgh said that the challenges faced by developed and developing countries alike made such a joint venture a global imperative. "The US notes, therefore, with pleasure the declaration of Bucharest (see page 620) in which the developing countries reaffirmed their willingness to work with a sense of urgency to assure the success of this conference", he said.

Science and technology should be used to help bring forth a threefold harvest: in the realm of reason, the realm of reality and the realm of rights. Efforts made in the real of reason were not a zero-sum game, in which the gains of those who seek equality and parity would automatically register as a loss for those who possess more. "In this realm we can prove the mutual benefits thesis — that advances in any part of the world are for the benefit of all", he said.

David Dickson

Canada pledges increase in joint projects

The Canadian government has agreed substantially to increase the budget of the International Development Research Center (IDRC) to allow it so support a joint projects between scientists in Canada and research groups in developing countries.

Addressing the UNCSTD plenary session on Tuesday, M. Martial Asselin, recently-appointed secretary of state for the Canadian International Development Agency (CIDA), said that although the precise amount of funds allocated to this purpose is yet to be decided, it would be in the order of the one-third of IDRC's current budget — ie about $12 to $14 million, an amount equivalent to 1% of Canada's total foreign aid.

Although under its initial terms of reference, IDRC is permitted to fund joint ventures of this nature — which from the Canadian side could involve university research groups or scientists from federal or provincial laboratories — the vast majority of the center's current funds are spent solely on research efforts in the developing countries.

The new commitment will, according to the Canadian Government, provide a direct way of linking up the needs of developing countries with Canada's own scientific and technological capacities. It has yet to be decided whether there will be an expansion Canada's foreign aid budget new year. □

Time to drown your sorrows?

US scientists find carcinogen traces in Scotch whisky

US scientists have found traces of nitrosamines, one of the most potent known carcinogens, in six brands of Scotch whisky. A few months ago, similar traces were found in various types of beer.

In both cases it appears that the nitrosamines are formed during the drying of sprouted barley malt. The levels detected are small, less than two parts per billion, according to Dr David H. Fine and Dr E. Ulku Goff, who carried out a study as part of a project funded by the National Science Foundation.

However levels as low as 10 parts per billion of nitrosamines are known to increase the incidence of tumours in laboratory animals. The beer industry has already said that, although little is known about the effects of such low doses on humans, it is taking steps to eliminate the presence of nitrosamines. It expects to have a solution "within a matter of months".

A spokesman for the Distilled Spirits Council of the US said last week that there was a marked discrepancy between the results of the NSF study and measurements reported last year by the World Health Organisation in Geneva, which had found nitrosamine levels of less than 0.2 parts per billion in Scotch whiskies. The council said this difference "may raise questions about the accuracy" of the new measurements.

But Dr Lawrence Garfinckel of the American Cancer Society doubted that such small amounts of nitrosamines would cause cancer. The most significant factor for him was that many drinkers were also smokers; a synergistic effect could account for the increased death rate from mouth and throat cancers that had shown up in studies of beer, wine and whisky drinkers.

The brands of Scotch whisky said by the NSF study to contain nitrosamines are: Chivas Regal, Black and White, J & B, Ballantine's Sandy Scot and Cutty Sark. Nitrosamines were not discovered in White Label whisky, nor in 46 other alcoholic beverages that were also studied.

Press banned from conference

The press is to be excluded from a meeting to evaluate short term, *in vitro* tests for carcinogenicity, following a ruling by the conference's organising committee. A decision not to invite journalists to attend the October, 1979 meeting in Atlanta, Georgia was taken when some of the participants voiced fears that the attendance of the press at the event would have an inhibitory effect and restrict the usual scientific discussions on such occasions. It has been decided, however, that in view of media interest in the subject, information on the conclusions of the conference will eventually be issued in December, at a press conference to be held in Washington.

Decisions to exclude the press from important scientific meetings are not without precedent. Recently, COGENE, the Committee on Genetic Experimentations of the International Council of Scientific Unions attempted to ban the reporting of the proceedings of a meeting on genetic engineering at Wye College in Kent. (See *Nature*, **278**, 496, 1979). The directive announcing the ban was greeted with a storm of protest and COGENE were forced to reverse their decision. The criticism of a reporting ban could perhaps have been predicted, given the public interest in genetic engineering.

Carcinogens are also a subject which are much in the public eye, a fact given emphasis by the current proposals for their control being discussed by Government Regulatory Authorities in Europe and the United States. European regulatory authorities appear to be far more in favour of *in vitro* tests as a screening net for carcinogens than do their counterpart organisations in the US. The Environmental Protection Agency, for example, views these tests with some doubt.

In view of the importance of the short term tests, and concern about the variability in results reported from different laboratories testing the same chemicals, two scientists — Dr John Ashby of ICI's Central Toxicology Laboratory, Alderley Edge, Cheshire, UK, and Dr F.J. Serres, NIEHS, Research Triangle Park, North Carolina, U.S., decided to organise a carefully controlled study to evaluate short term tests. Ashby, with the resources and expertise of ICI to assist him, was responsible for the synthesis, coding and distribution of some 42 chemicals to be tested by 25 *in vitro* assays in various laboratories throughout the world (see *Nature*, **274**, 740; 1978). The results of this valuable collaborative programme will be discussed at Atlanta in October.

The one notable ommission in the list of participants in Atlanta is Dr Bruce Ames of the University of California. Ames, who developed the famous *in vitro* test for carcinogenicity which bears his name declined to take part in the Ashby/Serres study. The Ames test has, however, been evaluated in several laboratories along with other tests.

Few scientists involved with short term tests are unaware of the significance of the Atlanta meeting; Government Regulatory Authorities are similarly aware. Dr David Douglas, Head of the UK Health and Safety Executives unit for collating information on toxic substances referred to the Atlanta meeting as the one which would "take the lid off" the subject of short term tests.

The importance of the Atlanta meeting cannot be denied. It is this which makes the intended exclusion of journalists so controversial. It remains to be seen whether the organisers will have second thoughts and reverse their decision.

Alastair Hay

Hazards at work 'kill 100,000 a year'

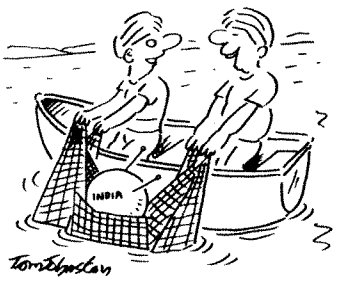
In a draft report to the President, the Toxic Substances Strategy Committee of the US Council on Environmental Quality claims that "more than 100,000 workers are believed to die each year as a result of physical and chemical hazards at work". The committee estimates that between 20% and 38% of all cancer may be caused, in part, by occupational exposure to carcinogens.

The report says prevention is the major key to controlling these environmental hazards and calls for the rigorous application of more than two dozen statutes for the regulation of toxic chemicals already on the books. It also advocated more legislation, including setting up a federal authority responsible for cleaning up hazardous waste sites.

More than 43,000 chemicals are listed by the Environmental Protection Agency as being subject to regulation. It may take years to determine whether or not a substance is hazardous and the complexities in reaching such a judgement are enormous. But the committee feels that the difficulties can be mitigated, to some extent, by greater cooperation between agencies involved in toxics-related research. The Government is to spend around $1 billion on toxics research next year.

The report has drawn some criticism from the chemical industry. The Chemical Manufacturers Association called it a "hodgepodge of concepts and recommendations that have been either disputed or discredited since the committe was created in 1977."

Anne Norman



news in brief

Windscale issues emergency advice: Residents living within a mile of the UK Windscale nuclear fuel reprocessing plant in Cumbria have been issued with leaflets explaining emergency procedures in the event of any serious incident there. Similar booklets have also been sent to farmers within 10 miles of the plant. The move follows a recommendation by Justice Parker — whose inquiry report last year gave the go-ahead for expansion at the plant — that local residents be informed of all emergency procedures. At first explantory leaflets were sent to local libraries and the media. Now these have been issued to the residents nearest to the plant to keep for reference. The booklets give details of evacuation plans, information broadcast procedures and medical arrangements in case of serious radiation leaks.

Harrisburg re-opening depends on residents' mental health: The mental health of residents living near the damaged Three Mile Island nuclear plant is a matter of "real and substantial concern" and should be carefully considered before allowing even the unaffected reactor on the site to be restarted, the US Nuclear Regulatory Commission has announced. Leonard Bickwit, NRC general counsel, said the commission felt that psychological, sociological and economic distress should all be considered in hearing the licensee's application to restart the plant, a decision unlikely to be taken by the NRC until the middle of next year. He added that a ruling on the mental health of residents could be a landmark in regulatory legal process.

This pronouncement contrasts with the recent publication by the operating company, General Public Utilities, of a plan to resume operations at the plant. This would involve venting into the air some of the radioactivity now contaminating the reactor chamber. However, although the quantities proposed would only involve releasing one tenth of a millirem of gamma radiation, compared with the 83 released at the height of the station emergency, it is unlikely the proposal will be given the go-ahead without strong legal and political opposition. And even if approved, it is unlikely that the plant could resume operations before June 1983.

Draft code to protect asbestos workers: A consultative document has been produced by the UK Health and Safety Commission on a proposed code of practice for workers dealing with asbestos insulation. The proposals are an extension and clarification of existing legislation. They include proposals for improving asbestos dust containment, waste disposal, personal protection and training for insulation workers. Industry and trade unions have until 30 November to give their view before a final code of practice is drawn up.

"Perhaps we'll have some benefit from our own technology now!"

Indian rocket crash: India's first rocket designed to put a satellite into orbit crashed into the Indian Ocean during a test flight. The launcher flew for only 15 minutes after blasting off from Sriharikotta space research centre in South India. The test failure is a setback for the Indian space programme which has been preparing for greater independence from the Soviet Union, whose launchers it uses at present. It was intended to put a satellite, Rohini Satellite-1, into orbit later this year using the SLV-3 rocket — which is similar to the US Scout rocket and uses solid propellants in all its four stages. Once the SLV-3 is successfully completed, India intends to launch a series of Rohini satellites — to be followed by a more ambitious programme of communications satellites.

Ariane delay: The first flight of Europe's independent space launcher, Ariane, has been postponed by about a month. The launch was scheduled for 3 November but because of problems with ball-bearing mounts for first and second stage engines, this has now been put back until the end of November or the beginning of December. However, a European Space Agency said the difficulty had not been a major one and had now been overcome.

African venereology conference opens: The first African International Conference on Sexually Transmitted Diseases was due to open at Ibadan University, Nigeria yesterday. More than 200 doctors and researchers were expected to attend and the opening speaker, Dr Duncan Catteral, described the event as "an historic day in African medicine". It had taken three years' campaigning to arrange the conference he said, and the agreement to stage it indicated that the African governments now recognised that sexually transmitted diseases were a major problem. Although no statistics were available, Dr Catterall believed the diseases were now widespread throughout the continent and there was an urgent need to develop a common policy towards treatment and contact tracing. In particular, the uncontrolled use of penicillin in many African countries was leading to the development of resistant strains which in future could prove very difficult and expensive to cure.

Two sponsors required for animal research under new Bill: Lord Halsbury's Bill on the protection of laboratory animals, due for its second reading in the House of Lords on 25 October (16 August, page 534), will require an applicant for a licence to do research on animals to have two sponsors, Lord Halsbury announced last week. One must be the applicant's supervisor, and the other an independent expert in the procedures to be used, who will also advise on alternative techniques. After the licence has been granted, the new licensee will have to work for a probationary period under the supervision of an experienced licensee. These rules will apply to those working with animals to produce vaccine and serums as well as those "experimenting" with animals.

The licensing of institutions where "procedures" on animals are carried out should ensure that stolen pets do not end up in laboratories, Lord Halsbury explained at a press conference on the Bill last week. The conference came to an abrupt end after interuptions from members of the Animal Welfare Society and the National Anti-vivisection Society.

Lord Halsbury's is not the only Bill on laboratory animals shortly to be considered by Parliament. Peter Fry MP will be putting another Bill to the House of Commons for its first reading shortly after the start of the next session.

US climate programme sets goals: Three major areas of activity — climate impact assessment, climate system research, and climate data, information and services — have been earmarked for the newly-established National Climate Programme, it was announced in the US. The programme was established by Congress last year and will coordinate the work of various federal, state, private, academic and international organisations. It is also planned that several experimental climate forecast groups should be set up as part of the programme, which will cost a total $114.2 million next year. These will develop, evaluate and test new climate forecasting methods.

Soviet cosmonauts land: Cosmonauts Vladimir Lyakhov and Valerii Ryumin have returned to Earth after a record 175-day flight aboard the Salyut-6 space station. First reports say they are healthy owing to an "exceptionally conscientious" attitude to exercise — unlike the ground crew, who according to Flight Controller A.S. Eliseev "have been suffering a certain amount of weariness".

India: the struggle for useful science

Are India's scientists "spoilt brats" who need to be put in their place? Or are they being manipulated by power-hungry politicians? *Anil Agarwal* reviews the beleagured state of science in India at the end of the two-year government of Mr Moraji Desai, who resigned as Prime Minister last month.

NEVER before was there more tension between the Indian government and the country's scientific establishment than during Prime Minister Morarji Desai's administration, which was catapulted into power in April, 1977, after the unexpected defeat of Mrs Gandhi at the polls. In October 1978, Mr Y.B. Chavan, the Opposition Leader in Parliament, took the unprecedented step of writing a protest letter to Mr Desai urging him to call an all-party meeting at the very earliest to discuss the problems created by the Janata Government's science policy. Mr Chavan said: "Science is a major national concern. It is not a party matter . . . our national commitment to science has been an agreed component of our national development policy right from independence". However, he alleged that since the Janata Party came to power, "several very disturbing developments have taken place . . . which have resulted in rapid demoralisation of the scientific community."

Mr Chavan criticised Mr Desai for permitting "foreign powers to make major inroads" into the country's nuclear programme and for unilaterally abjuring nuclear explosions even for peaceful purposes; for his totally unwarranted attack on the Council of Scientific and Industrial Research (CSIR) which in the face of a strong and unanimous reaction in the Parliament and the press, he had "to practically reverse" within barely three months; and, for mortgaging such vital sectors of the Indian economy as the aircraft and heavy electrical industries to Western and multinational interests.

Mr Chavan informed the Prime Minister that "we in the Congress Party believe that India's scientific and technological capability is a national resource, which any government whatever its political predilections, should cherish and develop to give strength to our country in a grimly competitive world."

For full thirty years, India was ruled by the Congress Party, first, under the leadership of Prime Minister Jawaharlal Nehur, and then, except for a brief period in the mid-sixties, under his daughter, Mrs Indira Gandhi. Both these leaders closely identified themselves with the scientific community. They made it a point to inaugurate every annual meeting of the Indian Science Congress; they would seldom miss an opportunity to visit a scientific laboratory or inaugurate a scientific seminar; and, they always kept in their Prime-ministerial portfolio such scientific departments as atomic energy, space and electronics to ensure that the department did not suffer from any bureaucratic constraints. Mr Nehru also set the tradition that the President of the CSIR would be the Prime Minister.

He believed that science was the only tool that could help India to eradicate poverty without a violent revolution, and therefore, tried to give the scientific community enormous prestige. Mrs Gandhi would always describe Indian S&T capabilities as the bulwark of India's self-reliance. During their combined regimes, R&D funding increased 353-fold — from Rs. 11 million in 1948-49 to Rs. 3887 million in 1976-77 (1 Rs = £ at 1979 prices) — and giant organisations like the CSIR (with 44 scientific institutions), Defence Research and Development Organisation (with 31), Indian Council of Agricultural Research (29), Atomic Energy Commission (7), Indian Council of Medical Research (8), Department of Science and Technology (18), Space Commission (5) and Electronics Commission (a funding and coordinating agency) grew up from scratch.

In 1977, the Central Ministries, public sector companies and State governments had another 327 R&D units; the private sector, 348; and 120 universities and institutes of technology were also conducting a variety of R&D projects. India had by then the world's third largest S&T manpower (only behind the US and USSR) consisting of 2.33 million, doctors, engineers, technicians and scientists. Over 53,700 professional were directly working on R&D projects in 1976-77.

Yet as far back as the mid-sixties, a feeling had started growing that India was not getting sufficient returns from this massive investment, particularly in industrial research. By the mid-seventies, Mrs Gandhi too occasionally began to chide Indian scientists for not conducting more relevant research. But the criticism of the Congress leadership was negligible compared to its praise. In a sense, it was a matter of vested interest for it to praise

Moraji Desai: some accused him of being anti-science

0028-0836/79/340625-01$01.00

©Macmillan Journals Ltd 1979

Indian R&D efforts, which, after all, as it rightly claimed, were there because of its own foresight. The vast urban intelligentsia, which grew up in the three decades of independence, (and which helped to sustain and drew sustenance from the Congress leadership) also came to see in these giant R&D establishments a sense of national achievement — a matter of pride for a developing country in a world where both political power and economic status essentially come out of the twin barrels of science and technology.

The new Janata Government was, however, not bound by this traditional association with Indian science, and, therefore, saw no reason to evaluate its achievements in muted tones. It immediately raised the question: have these organisations provided the country with benefits commensurate to the investments made in them? Dr Atma Ram, a former Director-General of CSIR, who was appointed by Prime Minister Desai as the chairman of the country's major science policy body, the National Committee on Science and Technology (NCST), explained in a recent lecture: "There is a vital difference between Morarji Desai's period and the periods of his predecessors. During the period of his predecessors, most of the expenditure in S&T was devoted to building up the institutional infrastructure . . . This phase has now given place to the next phase of assessing benefits from science. People want to know how far they have benefited from the science in which they have invested their hard-earned money. It is natural that the Prime Minister should pose such questions before the scientists."

But why should there be any basis for asking such questions? In thirty years, Indian industry has grown substantially. India today manufactures computers. nuclear reactors, textile machinery, pharmaceutical plants, heavy engineering goods, tractors and other sophisticated industrial products. But the bulk of this manufacturing activity is based upon imported technology, obtained through foreign collaboration agreements which by 1977 totalled about 5200. Direct foreign investment has remained restricted as a government policy but know-how has been imported from Eastern Europe and the USSR as much as from Western multinationals. India's own R&D institutions — even the national paper to the UN Conference on Science and Technology for Development admits — have played a very minor role in supplying the technology for this industrial development. The scientists and engineers in industrial establishments have themselves played a major and praiseworthy role in absorbing this imported expertise.

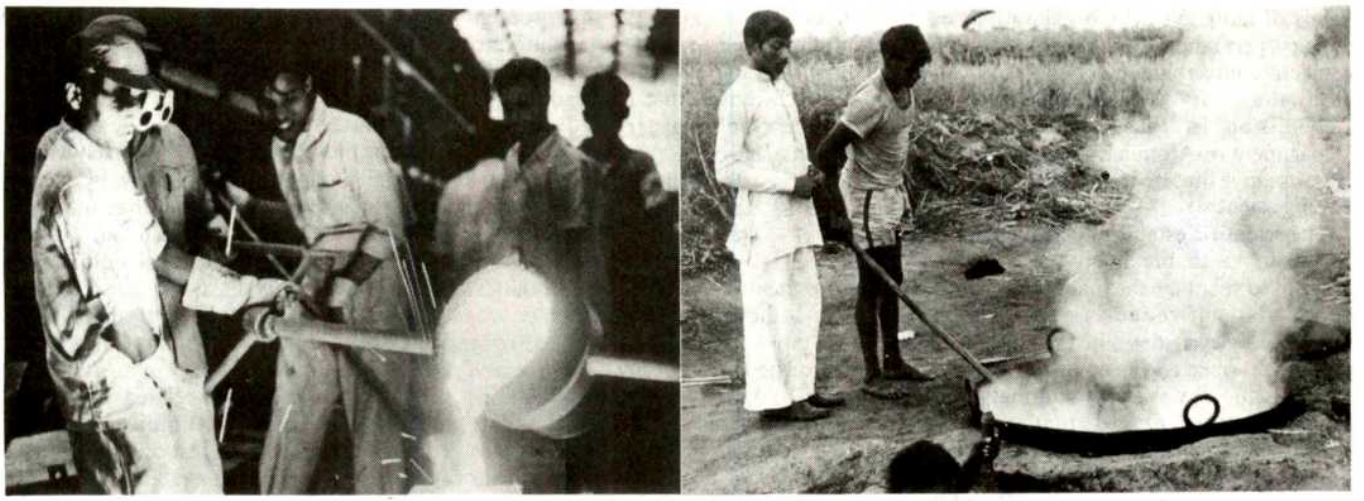
Take the case of Indian engineering goods for which the export trade has grown more than one hundred-fold — from Rs 52 million in 1956-57 to Rs 5517 million in 1976-77. These goods now constitute the most dynamic element of India's exports. India has also developed a series of its own mini-multinationals which have established several joint ventures with local enterprises in other developing countries. As the Indian government does not easily allow Indian companies to make foreign investments in cash, they have had to capitalise almost entirely on their know-how and equipment produced in India.

But why has the output of Indian R&D institutions been so poor? There are several reasons for this, and the main one is that Indian research institutions behave more like science laboratories than technology development institutions. They have failed to develop good links with prospective users of their know-how; they seldom carry their work beyond laboratory scale plants; most of them don't have adequate design and engineering capabilities; they seldom provide users with the software (raw materials procurement, credit, organisation, management, marketing, etc.) which is required to commercialise their hardware.

The Indian paper to UNCSTD admits in a milder language: "most Indian R&D agencies are much stronger in the generation of technology than in its delivery." But why is this so? Dr Atma Ram explains that "in those early days of the beginning of organised research efforts, there may not have been much understanding about the problems that would have to be dealt with in relation to the overall economic development of the country. There was perhaps a fascination for science, maybe a feeling of romanticism about it but not necessarily a clear and precise understanding of the mechanics of the application of science to economic growth and other spheres of national development. In other words, the necessary structure for research had been built with a noble but perhaps an undefined goal."

In March 1958, the Indian parliament had adopted a unique "Scientific Policy Resolution" (SPR) which was a declaration of intent by the people of India, as opposed to a resolution adopted by a particular government, to give sustained support to science. No other Third World country has ever made such a public commitment to science. The SPR was Prime Minister Nehru himself with some

T for Tata: assembly line in western India



Imported technology . . . exported trucks

One good example of an Indian mini-multinational is the Tata Engineering and Locomotive Company (TELCO), which is probably the first real Third World automobile multinational. TELCO even uses its own brand name. TELCO's joint venture in Malaysia assembles 7-ton 'TATA' trucks with components made by the parent TELCO in India. TELCO originally imported its technology from Daimler-Benz but now sells more than that company in Malaysia. It still does not have the capability to develop a totally new engine or a new vehicle. To manufacture a 13-ton truck in India, it has purchased a fresh licence from abroad. But through a well-organised technology assimilation programme, it extensively modified the 7-ton truck, concentrating on increasing its ruggedness and reliability — important attributes for bad road conditions in developing countries. Western companies meanwhile paid more attention to speed, driver comfort and emission control, which are of greater concern only in the developed countries. TATA trucks are, therefore, in demand in the Third World.

Apart from its Malaysian joint venture, TELCO has also licensed assembly of its trucks to companies in Indonesia, Egypt, Guyana and United Arab Emirates. Assembly of scooters (of a design originally imported into India from Italy) has been licensed by another private sector company to Taiwan and Indonesia. Meanwhile, the premier public sector company, Bharat Heavy Electricals Ltd (BHEL), which in the past obtained its technology from USSR, Czechoslovakia, UK and West Germany, is now independently setting up power stations, boilers and transmission systems in Malaysia, Libya, New Zealand, Saudi Arabia and Jordan, and competing successfully with big companies abroad.

Should technology be backing heavy industry or traditional rural processes like sugar making (right)?

help from the Chairman of the Atomic Energy Commission, Homi Bhabha. But it is noteworthy that the word 'technology' does not appear anywhere in the text of the SPR, nor does it reflect the distinction between science and technology and the need for technological innovation.

It is very difficult to make a cost-benefit analysis of an R&D organisation like the CSIR which also conducts basic research and occassionally plays an important role in increasing the bargaining strength of Indian enterprises while purchasing foreign know-how. Out of the total number of processes developed in Indian R&D institutions, up to 1974-75, 1293 out of 1726 were from CSIR and out of the total number of 729 inventions, CSIR had 607 to its credit. (Incidentally, defence laboratories which remain outside the realm of public scrutiny, had only 46.) But many CSIR processes remain unused. The royalty earned from processes released for commercialisation does throw some light on the return made from investments in R&D. Total royalties earned by the National Research and Development Corporation, which offers technology developed in Indian R&D institutions for commercialisation, came to Rs 5.2 million in 1976-77. The CSIR alone spent Rs. 413 million in that year on R&D.

Entrepreneurs, both in the public and private sector, have generally claimed that they are afraid of investing in 'half-baked' CSIR technology. They, therefore, exert pressure on the government to allow import of know-how from established foreign sources. R&D institutions, on the other hand, have always complained that the technology they generate is not used by industrial establishments because of vested interests in importing from abroad. Often these entrepreneurs have even been allowed to re-import the same technology. This results in unnecessary remittances of scarce foreign exchange, breeds technological dependence, and reduces the demand for indigeneous technology. In this way, both the country and its scientific community suffer. In a bid to stop such repetitive imports and encourage the use of local know-how, successive governments have allowed representatives of scientific establishments to participate in the various licensing committees, where they have the votes to stop any import of technology if it is already locally available, or it can be made available within reasonable time. But this practice has often led to delays in starting industrial establishments and is, therefore, not very appreciated by Indian entrepreneurs.

The Electronics Corporation of India Ltd, a public sector company that takes strong pride in indigeneous technology, was some years ago manufacturing and selling an outdated computer which was several times dearer than an equivalent computer abroad. The few components that had to be imported to manufacture it locally, were said to be higher than the total cost of a similar computer abroad. The Electronics Commission had to protest to the company about its price, as Indian users had no other alternative but to buy these computers because of a protected market. There is another case where a national laboratory offered to develop the technology for a public sector company to manufacture ferrites. The laboratory took several years to develop it, during which the country had to import the finished product in scarce foreign exchange. Finally, when the laboratory did supply the know-how, the company found that it still had to import the capital equipment.

Dr Atma Ram is a strong critic of unnecessary restrictions on import of know-how. It is "Made in India" and not "Invented in India" that matters ultimately for economic development. Indigeneous R&D, and import of technology, are not mutually exclusive, he says. "They are complementary. We need far more intensive efforts in R&D in areas in which technology is borrowed so as to adopt, modify and improve with the least possible delay."

Dr Atma Ram strongly criticised the restrictive approach to technology imports by the Electronics Commission arguing that the Indian electronics industry does not even compare with that of far smaller countries like South Korea, Taiwan and Hong Kong. "We are not a technologically illiterate nation," says Dr Atma Ram. "Our experts can be depended upon to make the best available choice and build upon it, provided they are suitably utilised." Japan, USSR, South Korea and now even China, are all buying technology. "My fear is," he told me, "that it is not a militarised China but an industrially powerful China that will soon begin to threaten India." Professor M G K Menon, a close confidant of Mrs Gandhi, has since relinquished his position as Chairman of the Electronics Commission and is now Director-General of CSIR.

Desai's battle to reorganise research

But it is not the transfer of Professor Menon as much as the earlier attempt by Prime Minister Desai to reorganise the CSIR that has drawn the real ire towards the Janata Government. A few months after he had assumed office, Mr Desai suggested that the CSIR had become too large for one Director-General to manage. Without any semblance of consultations with the scientific community at large, he got the Indian cabinet to accept the reorganisation of the CSIR. Under this plan, 28 CSIR institutions were to be split off and attached directly to their main user ministries. Each R&D institution would have become a separate registered society with the relevant Minister as its President to ensure the autonomy of the institution. Some senior officials of the Ministry would also become members of its governing body. However, when the news leaked out, the reaction was hostile. The scientific establishment immediately saw in it an attempt to erode its autonomy and make it subordinate to interfering bureaucrats. Indian scientists have traditionally despised generalist bureaucrats for their power in decision-making. To circumvent bureaucrats and ensure direct access to Ministers, Mrs Gandhi's government started the practise of making

0028-0836/79/340627-01$01.00

©Macmillan Journals Ltd 1979

heads of most scientific organisations ex-officio permanent secretaries of their respective government departments. The Chairman of the Atomic Energy Commission is, thus, secretary to the Department of Atomic Energy as well. Mr Desai's move thus revived a traditional fear among scientists.

The scientific establishment further saw in the move to break up the CSIR, an attempt to sabotage the main source of the country's self-reliance. Several left intellectuals even described it as a move that would open up the country's industry to domination by Western multinationals. Some scientists argued that the new government was trying to "cut scientists down to size" because of the good relations they had enjoyed with Mrs Gandhi's government — which indeed was true even during the authoritarian emergency days, when the scientific establishment rushed to show its loyalty to its political benefactors, probably more than any other professional group. Others dismissed the new government as basically anti-science, and conveniently used the government's interest in simple rural technologies and Mr Desai's own interest in traditional medical systems like auto-urine therapy, to illustrate their point.

It was soon clear that Mr Desai's government had not only ineptly handled the reorganisation proposal but also totally misjudged the symbolic national value that the CSIR held in the minds of the urban intelligentsia. It was a rare newspaper that supported the government. Several members of parliament also protested. Headlines screeched: "CSIR has been an eyesore to the multinationals" and "CSIR is the first martyr to the Janata Government's ill-concealed solicitude for the international giants."

As is usual in Indian politics, such charges are seldom accompanied by proof. While it is possible that the proposal could result in more harm than good — through greater bureaucratisation of the laboratories linked directly to Ministries and thus greater stifling of their scientists — it is difficult to imagine that Prime Minister Desai could have deliberately taken a decision to sabotage the country's self-reliance. I interviewed a series of senior scientists, many strongly opposed to the government's proposal, but none would say that Desai had wrong intentions. All agreed that the output of organisations like the CSIR needs to be both increased and improved.

However, the proposal was strongly supported by the bureaucracy because they could have surreptitiously helped those Indian interests who prefer foreign technologies and thus increase the influence of Western multinationals, explained a senior scientist working in one of the government departments. Once scientists came under the direct control of bureaucrats, they could no longer oppose their wishes. And it is among the bureaucracy, he alleged, that foreign technology-oriented industrial interests have considerable influence. The case of the research centre, that has traditionally been under the Minister of Posts and Telegraphs is cited. This centre has apparently done less to generate indigeneous technology and more to "sanctify the import of foreign technologies".

In the face of the unexpected political clout that the scientific community was able to muster, the proposal had to be scaled down. Finally, only four research institutes and, ten research associations were split off from the CSIR. The three museums under it were also transferred to the Ministry of Education. And it was decided that the reorganisation would be treated as an experimental measure, the performance of the separate institutions watched, and if so required, the decision could be reversed.

Getting more out of India's labs

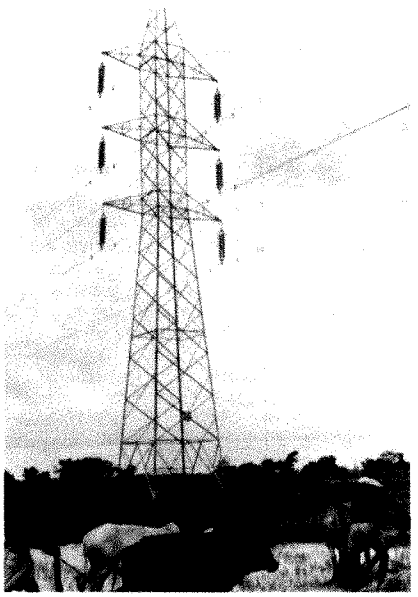
But whatever may have been the outcome of Mr Desai's proposal, it is important to note that his original question remains: how can Indian laboratories be coaxed to produce more? His was not the first proposals for re-organisation. Several committees like the Administrative Reforms Commission and Sarkar Committee of Enquiry into CSIR have also considered reorganisation. But none of the proposals have ever met with success. The scientific establishment itself has produced no proposals, nor even made any effort to come up with some.

The Indian scientific organisations are themselves extremely hierarchial and bureaucratic establishments, where success is often the result of patronage. Within these organisations, it is hard to find any semblance of enquiry or debate. Whatever may happen, the working scientists remain quiet. In fact, there is no evidence to show clearly how the scientific community (as distinct from the top establishment) reacted to Mr Desai's proposal. "Must scientists keep mum?", asked Surendr Jha, editor of *Science Today*, India's leading science journal, in an editorial. The government today provides nearly 90 per cent of Indian R&D funds. These funds have brought with them a financial and administrative culture, that has resulted in a stifling bureaucratisation of the R&D institutions. Scientists have turned into scientist-bureaucrats, appendages of a vast system of patronage and hierarchy. It is as if these big laboratories are like the Taj Mahals of Indian science, built to glorify and bury it.

In this bureaucratic system, the director-generals of the various councils and chairmen of the various commissions enjoy vast power and they take decisions without any reference to their own area of specialisation. Ward Morehouse, a US social scientist who has extensively studied Indian science policy, claims that these seven or eight scientists take virtually all the decisions in the world of Indian science. Committees are rampant in the decision-making procedure, and they are freely used to legitimise any whim or fancy by simply ensuring proper selection of their members — a practice that the Indian administration, in general, has imbibed in more than a full measure from Britain. Taking all the members of the NCST, directors of various laboratories, etc., decision-making of any national significance in science-related matters is restricted to about 200 individuals. The decisions made by the rest of the scientific community, if they make any, are of, at best, very local significance only.

It is not surprising that in this sytem, power and prestige usually comes to an Indian scientist when he leaves his laboratory, stops any R&D work directly, and turns into a science administrator. A study of Indian scientific and technical manpower engaged in R&D recently released by the Institute of Applied Manpower Research, New Delhi, reveals that only nine scientists out of 23,700 surveyed had a salary above Rs2,500 and 108 were in the scale between Rs2,250-2,500. Almost all of them were administrators. The apex for personnel engaged in full-time research lay below Rs2,500.

It is, therefore, easy to appreciate that such powerful and heirarchical establishments will strongly resist any reorganisation, whittling down of their empires, or even any effective science planning, for that matter. The best example of resistance to the latter is provided by the work of the first National Committee on Science and Technology, which was constituted in 1971 as a small and compact body of 10 members chaired by Mr C Subramaniam, then Minister of Planning and Science and Technology. The principal task of the NCST was, in the words of Mr Ashok Parthasarathi, then Mrs Gandhi's special assistant on science and technology, "to prepare a comprehensive science and technolocy plan, derived from and closely integrated with the fifth Development Plan (1974-79). This was the first time that a deliberate political committment had been made to integrate the economic, scientific and technological and educational dimensions of the development strategy into a coherent whole."



The members of this NCST were all young, middle-rank scientists, deliberately chosen to bring a breath of fresh air into science planning. But the giant organisations controlling agricultural research, defense research, atomic energy and space research, which consume the bulk of institutional R&D funds, made no serious attempt to co-operate. None of them wanted their areas of competence to be subjected to scrutiny by any committee outside. The NCST, too, recognising that it

Power plant deal that sparked off protests

One outstanding incident that attracted considerable public attention during Mr Desai's administration was the deal of the Bharat Heavy Electricals Ltd (BHEL) with the West German multinational, Siemens, to acquire know-how for a comprehensive range of heavy electrical equipment, including 200-500 MW coal-based power plants. The deal was expected to last 15 years, an unusually long period as the government generally frowns upon long-term collaboration agreements. Over 100 MPs and virtually every newspaper columnist again protested that this deal would make the country's electrical industry totally subservient to the foreign company. Part of the criticism emanated from pro-USSR MPs, who are piqued that BHEL was dumping technology that was originally acquired at easy terms from USSR. But many Indian public sector companies, who initially obtained know-how from socialist countries (often at critical moments when they had been totally denied access to know-how by Western sources) have in recent years sought collaboration with Western suppliers. This is because their technology demands have become more sophisticated, they themselves have

gained more bargaining strength, and because they are now looking for competitive export markets.

The Minister of Industries, George Fernandes, replied to the criticisms by pointing out that it was the Janata Government which sent IBM and Coca-Cola out of the country. His Ministry had promoted a drink developed by the Central Food Technology Research Institute, a CSIR constituent, to replace Coca-Cola. Moreover, the negotiations for the BHEL-Siemens deal had begun when Janata Ministers were behind bars, and therefore his government should not be described as "selling the country out to multinationals". He himself supported the deal as one that would be useful to BHEL. The BHEL board approved it and so did the Ministry of Industry and the inter-ministerial Foreign Investment Board. But when public pressure mounted up, he had to seek the approval of the Indian Cabinet. And when the Cabinet couldn't reach a decision, it was referred to a specially constituted committee of five Cabinet Ministers for further consideration. It is not certain now whether the deal will go through.

The BHEL-Siemens deal can certainly be criticised for its comprehensiveness as it does appear to leave little to challenge BHEL's own engineers. It could have been more selective and BHEL's know-how demands could have been tempered by the company first seeking to fully supply the Indian market instead of being excessively worried about gaining more export muscle. Many vital industrial areas like West Bengal and Maharastra are facing crippling power shortages. But the manner in which the deal has been questioned publicly gives the impression that many people believe Indian companies should be totally self-reliant for their technological needs. Except USA, there is no country in the world which generates itself even 10 per cent of the technology it uses. It is ironical that the atomic energy programme, which is held up as India's finest example of self-reliance, is really an example of a programme that is based on assiduously assimilated foreign know-how.

did not possess the muscle to take them on, concentrated mainly on the areas of R&D for which the CSIR is responsible. This too became possible apparently because the chairman of NCST was also then Minister in-charge of CSIR. As soon as the plan was prepared, the NCST was reconstituted and the young scientists replaced by the heads of the giant organisations. The simple explanation given was that the new NCST should rightly consist of the organisational heads as they are the people responsible for implementing the plan. But was that really the case? As the paper to UNCSTD puts it, the plan soon became "a useful check-list of programmes and projects", and that "suitable mechanisms for their implementation, monitoring and review could not be devised till the middle of the fifth plan (1974-79)." Some 2000 scientists had been involved in the preparation of the NCST plan, which was so easily, more or less, scuttled.

The next chairman of the NCST, Mr P N Haksar, seldom convened the reconstituted NCST, and, in fact, after a long delay, when he did, he asked it to discuss for a whole day whether there was a need for such a committee. As he put it, there were already so many barons to take care of Indian science. The NCST was, thus, soon reduced to a dormant state. Until, of course, Mr Desai appointed Dr Atma Ram, a close confidant, as the third chairman, and then unpleasant decisions like the reorganisation of the NCST and review of the Electronics Commission began to be taken.

Prime Minister Desai certainly refused to acknowledge the need for the all-party meeting suggested by Mr Chavan and challenged "anyone to prove that the transferred institutions are not closely and intimately connected with the policies and programmes of the Department concerned." "I would go so far as to say," he pointed out, "that the scheme of reorganisation promotes the country's commitment to using science for national development." But despite this bold face, the Janata Government became increasingly defensive. Both Prime Minister Desai and Dr Atma Ram, chairman, NCST repeatedly pointed out that the Janata Government was neither anti-science or anti-scientists, and that actually increased the R&D budget from Rs3,887 million in 1976-77 to an estimated Rs4,767 million in 1978-79. The Prime Minister's speech to the Indian Science Congress in 1979 is reported to have been largely drafted by Professor Menon instead of Dr Atma Ram.

The lack of communications between the government and the Indian R&D community has come at an inopportune time. Something that Indian scientists have always wanted, an R&D culture in the industrial establishments themselves is now steadily growing. Many large public and private sector companies have set up their own R&D units. Science organisations like the CSIR now not only need to increase and improve their output, but also begin to co-ordinate their work with these units and even slowly begin to reconsider their long-term role in Indian R&D. As industries begin to undertake routine industrial R&D themselves, R&D institutions could possibly move into more sophisticated and forward-looking basic and applied research that is required to support industrial R&D. In the present state of disarray, there appear to be very few science planners thinking at all, particularly in the scientific establishments.

The incidents during the Desai administration show that the scientific establishment can muster enormous political clout in a developing country. But, unfortunately, in the Indian case, it is behaving more like a pampered and spoilt super-brat, who immediately turns nasty when its ears are tweaked. But questions of public accountability in India will certainly arise again. □

Fast reactor safety

SIR, — In his article on fast reactor safety (26 July, page 270) Norman Dombey claims to introduce to non-specialists some features of fast reactors that are not available outside the technical literature. The non-specialist would do well to treat this article with caution as it contains a number of errors (some of them elementary) and is more likely to mislead than to inform. The following is a list of some of the more outstanding errors:

- "Thermal reactors are designed to be in their most reactive nuclear configuration". This is incorrect and some examples were given by Professor F.R. Farmer (12 April, page 593). Some reactivity coefficients in thermal reactors are positive and are not all negative as stated — indeed gas-cooled Magnox reactors have operated safely for over 20 years with strongly positive moderator temperature coefficients.
- "Thermal reactor has less than one critical mass" This is incorrect: all reactors have to have at lest one critical mass.
- "So in a fast reactor of the design envisaged in CFR1 . . . there will be no overall negative Doppler coefficient" The reasoning and the conclusions are both incorrect and there is in fact a strong negative Doppler coefficient which is a major contributor to the safety of the reactor. (I have now seen the erratum (9 August, page 444) which corrects this point.)
- "For example a coolant channel gets blocked, sodium boils . . . pieces of plutonium fall and form a molten mass which if large enough can become prompt critical!" This is incorrect. The reactivity effect of voiding a single channel is so small that there would be little effect on the power level in the rest of the core. There is insufficient fuel in a single fuel sub-assembly to produce criticality even if all the fuel pins in it were melted and compacted.

There are other incorrect technical statements: for instance, sodium is more easily contained than high pressure water or steam and is not as corrosive to reactor constructional materials; and the delayed neutron fraction, on which the normal control behaviour of thermal reactors as well as fast reactors depends, is nearly twice as great as stated (and is always greater in a fast than in a thermal reactor with the same fissile material).

These errors are important in that they convey the impression that fast reactors are difficult to control, unsafe and not well understood. On the contrary the fast reactor in normal operation has no tendency to become unstable and can be left for hours without any adjustment of the controls. Temperature and power control is simple, straightforward and easy to engineer to very safe standards. Their safety has been the subject of intense study for very many years and it is well understood. Clearly there will continue to be work related to the detailed choice of safety features until licensing rules have been formulated and as with other reactor types the preferred selection of intrinsic and engineered safety features will be clarified during negotiation of the licence for the first commercial reactor. What is important is that fast reactor designers are confident that they can meet safety standards at least as stringent as those applied to other reactor types. Furthermore any design features incorporated for safety reasons are not likely to increase the expected cost by more than a few per cent.

The economic statements are equally ill-founded. The increases in the capital cost of SNR 300 were due largely to late changes in the design requested during the complex licensing process which was being developed using SNR 300 as a guinea pig: even if the changes incorporated in this way were thought to be necessary for later reactors the cost of including them *ab initio* would be small compared with the costs of SNR 300.

Whilst the capital cost for a fast reactor appears to be inherently higher than for a thermal reactor — estimates range from as low as 1.1 times to about 1.5 times or perhaps approaching 2 times for the first-off commercial sized demonstration plants — there is little doubt that the lower fuel cycle costs will more than compensate as uranium prices increase, due to pressures in the next few decades on the limited supplies of uranium ore. The breakeven point could well be before the end of the century, which is the timescale for planning exploitation of the fast reactor system. Remember the fast reactor will produce about 60 times more energy than a thermal reactor for the same quantity of uranium. Commercial designs are of course being developed to meet safety requirements which are included in cost estimates, and the implications by Dr Dombey that designers have to suddenly take them into account after the rest of the design is complete shows a lack of understanding of the attitude of design engineers to safety.

Despite his failure to reach it by logical argument, Dr Dombey's general conclusion that the UK should continue to collaborate as closely as possible with other countries in developing the fast reactor is commendable and has been stated on many occasions to be current policy. Articles which undervalue the extent of the UK's possible contribution to such a collaboration are not likely to be of assistance in such collaborations.

It is disturbing that the article contains so many inaccuracies, which, compounded with the error about the Doppler Coefficient, gave such an unbalanced view of fast reactor safety at a time when an impartial academic view would have been particularly valuable.

Yours faithfully,

R.D. SMITH

Fast Reactor Development Directorate, UKAEA, Risley, UK.

Domestic animals are not inferior

SIR, — Mellanby (*Nature* 275, 82; 1978) attacks opponents of 'factory farming' for their errors in animal behaviour, as well as for their own behaviour at his talk. First, while not wishing to justify the human behaviour he describes, it should be borne in mind that many in the environment movements have suffered far worse behaviour at the hands of establishment figures — treatment not all that different from what is meted out to dissidents in the socialist world, well detailed in the columns of *Nature*.

Second, there are scientific, practical and humane reasons for objecting to some aspects of intensive husbandry. Those who are critical of such practices do not get their views published — in contrast to the regular columns in *Nature* by such strong advocates of 'factory farming' as T. H. Jukes and Mellanby.

Third, since Mellanby frequently (and rightly) complains of occasional errors and oversimplifications made by environmentalists may we have the opportunity of correcting some of his.

The statement by Mellanby, "Domestic animals, cattle and sheep, and pets such as dogs and cats only exist because man breeds them . . . but if man disappeared from the world, so would most domestic animals" seems at variance with his later comment about the feral cat " . . . endangering the native fauna . . .". Both statements are misleading.

The feral cat in Australia largely has the rabbit as its major prey (Coman, B. J. and Brunner, H., *J. Wildlife Management* 36, 848; 1972). Habitat destruction by man is the major threat to Australian native fauna (Marshall, A.J., *The Great Extermination;* Hienemann, Melbourne 1966).

In reviewing literature on the success and failure of introduced animals, we find that there is no statistically significant difference between domestic and wild species in regard to successful establishment in the absence of human care. Indeed, some major animal domesticates, notably goats, pigs, cats, dogs, and rabbits become successful in a variety of habitats and resist sustained human efforts at control or eradication.

The idea that domestic animals are inferior and degenerate — and thus less deserving of humane attention — is widespread. It is dangerous to confuse science and value judgements, however, and it is worth bearing in mind that Konrad Lorenz justified his support for the German 'eugenics programme' on the basis that man was becoming domesticated (Haldane, J.B.S. in *Culture and the Evolution of Man;* Galaxy Books, Oxford University Press, New York, 1962 and Nisbett, A., *Konrad Lorenz;* J.M. Dent, London 1976).

Yours faithfully,

C. M. ANN BAKER
CLYDE MANWELL

Selby, Yorkshire, UK.

Brazilian official was illegally dismissed

SIR — I wish to congratulate you for the story on the Brazilian exiled scientists (26 July page 268). I would only like to rectify a misquotation concerning my husband, an ex-official of the Brazilian Parliament who was illegally dismissed for political reasons when the military took over in 1964, and was not "an ex-deputy whose mandate was annulled", as published.

Yours faithfully,

ALICE RIVERA

CNRS, Gyf sur Yvette, France.

What use is scientific awareness?

SIR — your concern for the lack of scientific awareness of the British public is comendable (9 August, page 435), but may I ask to what end? As an unemployed maths teacher who has never held any scientific or technical position, I am probably as close to the "general public" as your regular readership extends. I try to keep myself informed on all branches of science, and my general scientific awareness is far greater than could ever be reasonably expected as a norm. I think it is worth noting that as far as I know this awareness has never been of the slightest benefit to anyone.

Yours faithfully,

R.J. SALISBURY

Anglesey, Wales, UK.

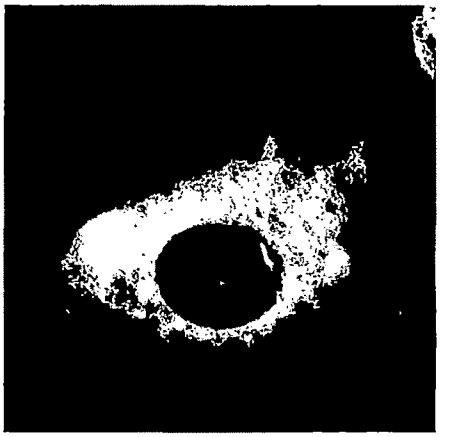
Primitive model for cell cycle control

from Clive Lloyd



IN non-motile cells of multicellular organisms atypical, internal cilia form from the centriole. The role of these so-called 'primary' cilia in such cells is unclear but recent work shows that nevertheless they may provide a useful indicator of the state of the cell cycle.

The centrioles appear in different guises at different stages in the eukaryotic cell cycle. During the division of most animal cells for instance, they are associated with each pole of the mitotic apparatus. They may, however, merely be passengers during this process, since amorphous pericentriolar material seems to be the major nucleation site for those microtubules formed at the poles of the mitotic apparatus (Gould & Borisey *J. Cell Biol.* **73**, 601; 1977). By contrast, the role of centrioles in non-dividing cells is less ambiguous for they act there as pre-formed templates (basal bodies) for the outgrowth of the microtubules which form cilia and flagella. Cilia and flagella are generally thought of as organelles of motility; propelling unicellular organisms through the environment or moving the environment over the surfaces of tissues (see *Cell Motility* (eds Stebbings & Hyams) Longmans, 1979). However, atypical, internal cilia are also seen associated with the centrioles in non-motile cells of multicellular organisms.

These internal cilia differ from the motile variety in several ways. Motile cilia/flagella generally consist of a bundle of nine outer doublet microtubules surrounding two singlet microtubules, but the internal cilia have a 9+0 instead of a 9+2 arrangement (Barnes *J. ultrastruct. Res.* **5**, 453; 1961). In addition, the 9+2 cilia possess a basal organisation involving only one centriole or basal body, whereas cilia possessing twinned basal structures generally display a 9+0 pattern (although the converse may not necessarily be true). The 9+0 cilia have been referred to as 'primary' since Sorokin (*J. Cell Sci.* **3**, 207; 1968) first noted that they were produced in bronchial epithelial cells before the 9+2 type which make up the ciliated border.

As for their function, primary cilia have been observed at the site of regrowth of cytoplasmic microtubules in 3T3 fibroblasts (Osborn & Weber *Proc. natn. Acad. Sci. U.S.A.* **73**, 867; 1976) (see figure) and are aligned with the current track of migration in such cells (Albrecht-Buehler *Cell* **12**, 333; 1977). This could imply some function for the primary cilium in influencing cell polarity, but Albrecht-Buehler is careful to point out the difficulty of sorting out cause from effect in such observations. Perhaps primary cilia serve no useful purpose. Found in unicellular and multicellular organisms alike, the centriole may be part of a primitive motile system and in differentiated, non-motile tissue cells, the 9+0 cilium on the centriole may be vestigial — representing a throw-back to a unicellular, free-swimming mode of existence.

However, even if it is now redundant, the cyclic formation and disappearance of the primary cilium still provides clues to cell cycle control. As long ago as 1898, it was suggested that the transformation of centrioles into ciliated or flagellum-bearing basal bodies could be one of the control mechanisms for the regulation of mitosis and differentiation (Henneguy *Arch. Anat. Microscop. Morphol. Exp.* **1**, 481; Von Lenhossek *Verh. Anat. Ges. Kiel.* **12**, 106). This theme was revived by Rash *et al.* (*J. ultrastruct. Res.* **29**, 470; 1966) who, studying cardiac differentiation, reasoned that "the blockage of mitosis usually associated with the initiation of cytodifferentiation can be correlated with the formation of cilia and may be mediated by the transformation of the mitotic centrioles into ciliary basal bodies." Several reports agree with this: primary cilia do not occur in mitotic BHK fibroblasts, but reappear soon after division (Archer & Wheatley *J. Anat.* **109**, 277; 1971); they are more frequently observed in differentiated, non-dividing brain tissue than in dividing tumours or juvenile tissue (Dingemans *J. Cell Biol.* **43**, 361; 1969); primary cilia are observed in rat liver cell cultures only after their growth has been arrested in the post-mitotic phase of G_1, and not before (Mori *et al. Expl. Cell Res.* **120**, 435; 1979).

Immunofluorescence micrograph of 3T3 cell stained with antibodies against tubulin. The cell has been treated with colchicine to destroy the microtubule network and the primary cilium is clearly visible. Magnification × 900. (From Osborn & Weber *op. cit.*)

Now, in a recent paper (*Cell* **17**, 527; 1979) Tucker, Pardee and Fujiwara map out the timetable of centriole ciliation and deciliation in 3T3 fibroblasts and suggest that a correlation exists between the centriole cycle and the cycle of DNA replication and chromatid separation which is a more familiar feature of the cell cycle. Using indirect immunofluorescence, Tucker *et al.* confirm that centriole ciliation occurs when cells are arrested by conditions of low serum or high cell density in the post-mitotic phase of G_1. When stimulated to divide by the addition of fresh serum, this unduplicated centriole deciliates within 1–2 hours, reciliates by 6–8 hours and undergoes a further deciliation between 12–24 hours which roughly coincides with the initiation of DNA synthesis. The microtubules of the mitotic spindle form part of an apparatus for dividing genetic material between sister cells and so it may not be surprising that microtubule and nucleic acid cycle are somehow coordinated. As these investigators point out, microtubule-

©Macmillan Journals Ltd 1979

organising centres (for example the centriole and, probably, its associated material) seem to be diverted from alternative activities in preparation for mitosis at about the time that DNA replication is initiated. This is reminiscent of the sequence of events which occurs in the division cycle of the yeast *Saccharomyces cerevisiae* (Hartwell *Bact. Rev.* **38**, 164; 1974) where mutation of the gene controlling the replication of the spindle pole body (a microtubule-organising centre analogous to the centriolar complex) blocks the initiation of DNA synthesis and hence of other steps leading to mitosis. The timing of centriole duplication in mammalian cells is not yet determined, but may occur in late G_1 or early S (see also Rattner & Phillips *J. Cell Biol.* **57**, 359; 1973).

Although a useful marker for some cells, primary cilia are absent from others and it should not be forgotten that higher plant cells may not possess centrioles (see *News and Views* **277**, 515; 1979). Higher plants do, however, possess amorphous microtubule-organising centres analogous to the amorphous type which surrounds the centriole in animal cells and plays a more direct part in forming the mitotic apparatus. Telzer and Rosenbaum (*J. Cell Biol.* **81**, 484; 1979) have isolated such pericentriolar material from HeLa cells and demonstrate that when isolated from mitotic cells it supports reassembly of microtubule protein into microtubules, but is ineffective when obtained from cells in interphase. Considered together, recent evidence points to a close association between the activity of microtubule-organising centres (both structured and amorphous) and the mitotic cycle. In view of this it may be useful to consider even the cells of multicellular organisms as 'differentiated flagellates' which undergo a metamorphosis to the reproductive stage driven by signals affecting microtubule organising centres. □

Immunotherapeutic T cells?

from Peter Beverley

TWENTY years ago Thomas proposed the theory of immune surveillance. Since then it has been a hope of cancer immunologists that the immune system might be persuaded to do the work of physicians and surgeons and destroy the tumours of cancer patients.

Initially, because of their role in allograft rejection, thymus-derived lymphocytes (T cells) were thought to be the main agent of surveillance. Later data have thrown up other candidates for the role of 'surveyor' (Baldwin *Nature* **270**, 557; 1977) and the very idea of surveillance has been challenged (Moller & Moller *J. Natn. Cancer Inst.* **55**, 755; 1975). Nevertheless T cells remain an attractive possibility for immunotherapy because of their extreme specificity of response and because high levels of activity can be generated by stimulation *in vitro*.

The practicality of immunotherapy rests on a number of assumptions. First that tumours carry surface antigens distinct from those of normal cells; second that lymphoid cells of the tumour-bearing host can be immunised against the tumour antigens; and third that immune cells (or antibodies) when administered to the tumour-bearing animal will be effective in reaching and destroying the tumour.

Experimental tumours often provoke an immune response, but in many cases it has been shown that immunity is directed against antigens coded by RNA tumour viruses carried in the tumour cells, while in general the evidence for immunogenic antigens on spontaneous tumours of animals is far weaker. In man apparently, tumour-associated antigens have been defined using heteroantisera but it is not clear whether these antigens provoke a T cell response by the tumour bearer. Similarly, although there have been many reports of cell-mediated immune responses to tumours in man, their exact nature and specificity have been difficult to define because the responses are weak and inconstant. Thus the two findings that T cells cytotoxic for human leukaemias could be generated (Sondel *et al. J. Immun.* **117**, 2197; 1976) and that specific cytotoxic cells could be propagated indefinitely *in vitro* (Gillis & Smith *Nature* **268**, 154; 1977) raised the hope that some of these problems might be resolved by the production of large numbers of highly active cytotoxic T cells directed at human tumour antigens.

This has now been achieved by Joyce Zarling and Fritz Bach, (this issue of *Nature*, page 685) and the power of the new methodology is certainly demonstrated. Previously, not all leukaemia patients could be shown to respond to their own leukaemia cells (Lee & Oliver *J. exp. Med.* **147**, 1334; 1978) but a combination of stimulation *in vitro* followed by expansion of the cytotoxic T cell population *in vitro* (up to 10 million-fold) reveals that virtually all patients can make an immune response to their own leukaemia cells. Furthermore, since stimulation with a pool of allogeneic lymphocytes was effective in generating kill against autologous leukaemia cells, it may be possible to generate cytotoxicity against a tumour even if no tumour material is available (important for immunotherapy of solid tumours where stimulator cells may be hard to obtain). That pooled allogeneic cells are effective reinforces the immunologists' dogma that transplantation antigens (HLA) in some way determine or are related to the T cell repertoire.

On the face of it the finding that T cells can be sensitised to autologous leukaemia cells and that other cells are not killed would seem to be strong evidence for tumour-specific antigens on leukaemia cells. However, this is a conclusion which should be regarded with considerable suspicion. Recent studies of leukaemia cells from many laboratories suggest that at least the majority of leukaemias have surface membrane phenotypes characteristic of normal, though sometimes rare, cells. A cautionary tale is provided by the acute lymphoblastic leukaemia (ALL) antigen which, although first discovered on leukaemia cells and thought to be ALL specific is in fact found on bone marrow stem cells in fetal and regenerating bone marrow (Greaves & Janossy *Biochim. biophys. Acta* **516**, 193; 1978). As yet no controls carried out in studies of autologous anti-leukaemia cytotoxic T cells have proved that the target antigen(s) for the killer cells are not just the same sort of normal differentiation antigen. If immunotherapy involved elimination of a stem cell population along with the leukaemic cells it might not be so attractive a proposition!

Delivery of immunotherapy is an additional problem. In animal experiments immunised cells have been most effective when administered mixed with tumour cells in local tumour growth assays. The relative inefficiency of systemically administered cells may be due either to incorrect migration *in vivo* of cultured lymphocytes or because more than one subset of lymphocytes is required for optimal elimination of tumour cells.

Even if there remain doubts about the use of T cells amplified *in vitro* for therapy, there can be no doubt that cultured T cells will be extremely useful tools. Not the least important of the questions which will surely soon be answered, doubtless using cloned sublines of killers, is what is the nature of human leukaemia antigens? If they turn out to be exclusively tumour-associated, the way to T cell immunotherapy may be open. □

Conserving genetic resources of animal species

The idea of the botanical gene bank, where seeds of rare and endangered plants are kept dormant in the deep freeze, to be revived when required, is now widely accepted. Here Dr B.N. Veprintsev of the Institute of Biological Physics and Dr Natalia Rott of the Institute of Developmental Biology of the USSR Academy of Sciences, argue that similar gene banks should be started immediately for rare and endangered animal species and speculate on how it might be possible in the future to reconstruct extinct animals from their germ cells stored in such a bank.

WE are witnesses today to radical changes in the environment — the disappearance of virgin forest and prairie and the exploitation of hitherto undisturbed oceans, lakes and rivers. The disappearance of many animals and plants is an inevitable consequence of the loss of their natural habitats. Their loss would not only produce an aesthetically impoverished landscape but, more practically, eliminate important genetic resources and disrupt the stability of fragile ecosystems which have evolved over the centuries. The rate of change is accelerating rapidly. If we do nothing to save rare and endangered species now it will soon be too late.

Current efforts to preserve rare animals and plants in natural reservations, zoos and botanic gardens may not provide sufficient security for their future. We believe that we must find ways of conserving the basic genetic material of these species — the gonads, germ cells and somatic cells — so that they can be revived in the future when conditions for their survival may be more favourable.

We should like to propose various ways in which animals might eventually be reconstructed from the conserved genomes (Fig. 1). To put this hypothetical scheme into practice we need:

- to preserve the genetic information of endangered species in as complete a form as possible.
- to find ways of realising this information by obtaining zygotes and rearing animals from them.
- to find ways of changing the sex of some of the reconstructed animals if they are all of the same sex, as would inevitably follow from some of the methods proposed.

Sources of genetic information

The most realistic approach at present is to store frozen gonads, germ or somatic cells for subsequent reconstruction of zygotes. One immediate problem of course is how to obtain such material without further endangering the population of rare animals. In our opinion the most suitable cells for conservation would be the germ cells (oocytes and spermatozoa) and fertilised ova — the zygote itself before reduction cleavage.

For some species somatic cells might be an attractive genetic source as they are easily collected and some at least could be expected to contain all the necessary information for development.

Storage

Deep freezing seems the best method of conservation at present. Already deep frozen sperm are widely used in animal breeding and more recently, methods of storing deep-frozen oocytes and embryos of cattle[1,2] and some laboratory animals[3] have been developed. Oocytes can be stored in gonadal tissue culture and in deep frozen gonads[2-5] and subsequently can be matured either by implantation of the gonad into a female recipient[5] or by hormone treatment *in vitro*[4,6].

Reconstruction of a viable zygote

The means of obtaining a viable zygote from the stored material must of course be the most speculative part of our scheme. In normal development, the interaction of the zygote nucleus with its cytoplasm is necessary for the proper expression of the genetic information. In differentiated somatic cells, however, although the nucleus contains a complete set of genetic instructions, most genes are not expressed[7]. Therefore, in order to regenerate an animal from its conserved genome, it is necessary to provide an environment in which the genetic information is expressed as in normal development.

If we have only been able to conserve spermatozoa, one approach would be to fertilise the ova of a closely related species. The success of such interspecific hybridisation varies in different animals. In birds and fishes, hybrids between different genera and even families are possible. In mammals and amphibia interspecific hybridisation can take place. In cases where spermatozoa cannot fertilise the ova of another species this difficulty might be overcome by injecting the sperm, treated with proteolytic enzymes, directly into the ovum cytoplasm[8]. In some cases hybrid incompatibility might be overcome by obtaining tetraploid and amphiploid hybrids in which two chromosome sets belong to one species and two to the other. Such hybrids have been obtained in frogs and silkworms[9]. In all cases where the genetic material of two species is mingled, the required species would have to be re-established by repeated backcrossing of hybrid females with male sperm of the original species.

Another possibility might be androgenesis. This would avoid the problem of backcrossing to eliminate unwanted genetic material. Just as complete plants can be regenerated from male pollen alone, it might be possible to fertilise an ovum of another species, in which the nucleus had been inactivated, with the sperm of the desired animal. In this case one would obtain an, admittedly haploid, zygote, in which the genes were those of the required species but the supporting cytoplasm was of a different species. To get a diploid zygote two male

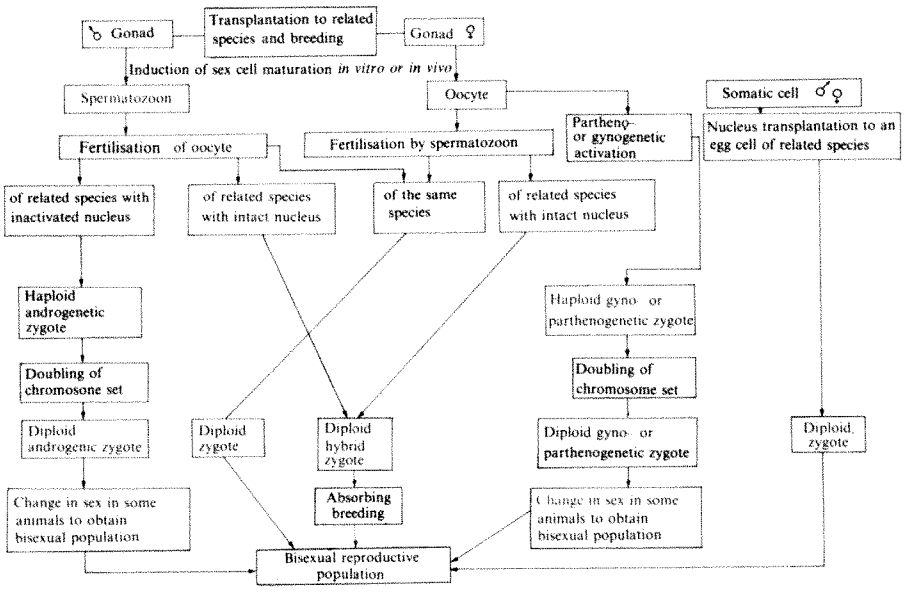

Fig. 1

©Macmillan Journals Ltd 1979

nuclei would have to fuse (dispermic androgenesis), and unfortunately so far this is known only in silk-worms[10] and axolotls[11]. Alternatively zygotes might be made diploid by inhibiting one of the primary cleavage divisions[12], but the resultant homozygous embryo might reveal lethal or undesirable recessive genes[13,14].

If only oocytes were available these might be induced to undergo parthenogenesis by chemical activation or by pseudo-fertilisation with sperm of a different species which cannot subsequently take part in development. A diploid embryo could again be obtained by inhibiting either one of the maturation divisions or one of the first cleavage divisions[14]; the problem of homozygosity remains.

If only somatic cells were available, perhaps the nuclei could be transplanted into the fertilised zygote of a closely related species, in which the nucleus had been inactivated. Experiments with amphibia of the same species have shown that in such cases normally inactive genes are reactivated and normal development proceeds. Microsurgical nuclear transplantation is succesful in amphibia, fish and insects, and some limited success has been achieved with mammalian material[15]. Nuclei for one species can also be introduced into cells of another by cell fusion, brought about by Sendai virus or polyethylene glycol[2].

But nuclear transplation from one species to another has proved very difficult. In the many experiments which have been done, hybrids have been obtained in only four cases, and in two of them the oocyte nucleus remained in the recipient cell[15]. In most cases the embryos did not develop. Producing chimaeric embryos may help to overcome this difficulty. The cells of lethal hybrids were shown to have increased vitality when fused with the embryos of a normal parental species[17]. But although chimaeric mice can be produced routinely by aggregating two very young embryos or by injecting cells from one into the other, attempts to obtain interspecific chimaeras present more problems.

Zygote development

How might reconstructed zygotes be reared to produce living animals? In insects, fish and amphibia this is not particularly difficult but for reptiles, birds and mammals the problems are enormous. No-one has yet achieved the complete development of such an embryo *in vitro*. In every case in which manipulated embryos have been successfully reared, they have been reimplanted into the mother or into a fostermother of the same species.

The most reasonable course in our scheme would be to transplant embryos 'conceived' *in vitro* into foster mothers of a closely-related species. However, attempts to do this — mouse into rat for example — have so far failed. The reasons for failure are unknown. There may be immunological rejection of the embryo; in this case it might be possible to induce tolerance. This would need suitable antigens from the 'preserved' species so we need to conserve not only gonads and germ cells but other tissue as well. For birds and reptiles interspecific ovarian transplantation seems very attractive.

Sex determination

Some of the methods outlined above (parthenogenesis and gynogenesis for example) would produce animals all of the same sex, so it would be necessary to look for some way of converting some of them into the other sex. Mechanisms of sex determination differ from species to species so any treatment would have to be individually tailored. This may be less daunting than it seems, for there are species, for example among the fishes and amphibia[16], that change sex spontaneously. And in other species hormones and other factors can influence sexual development.

Although most of the methods we have discussed are not yet practicable, research is proceeding at such a rate that they are beginning to look feasible in the not-too-distant future. Semen, blood and skin tissue from rare animals in zoos could be collected and stored without any danger to the animal itself. So we urge that collection and storage of suitable material should start now. But we need to be very cautious and not think that this approach can save the animal kingdom. It must be only one necessary step among many measures needed to meet the present emergency. □

The impact of climatic change

from Martin Parry

OUR knowledge of fluctuations of climate has exhibited a precocious flowering in the past 5 years and the time has come to consolidate the progress already made along many different paths and to point a way forward. This was the goal that 250 climatologists and historians from 33 countries set themselves recently at the conference on Climate and History at the Climatic Research Unit, University of East Anglia*.

The issues that emerged from this meeting touched on many facets of contemporary economics and society, in addition to the more specific problem of the impact of climate in history. The latter will be reported in detail elsewhere, but a number of points that were raised in papers and highlighted in discussions had far-reaching implications and deserve immediate debate. The points can broadly be divided into those that derive from a greatly increased understanding of the scale, direction and timing of climatic fluctuations, and those that are related to the economic and social impact of such fluctuations.

The reconstruction of past climates has benefited from the recent advances made both in the quarrying of new data sources and the improved analysis of existing ones. At the University of Bern, Christian Pfister has recently developed a new set of procedures for standardising and storing a great variety of data, from weather descriptions in farming diaries to dates of lake freezing and the size of vine harvests. The system could provide the basis for an integrated and international pool of data — a pool to which information from new sources could continually be added. Several new data sources were mentioned at the conference, including tax records in Norway and meteorological records from China. At the same time, the improved 'calibration' of tree-ring data by Harold Fritts and his colleagues at the University of Tucson is giving us a vital bridge between the beginning of the instrumental records (about AD 1600 in Europe and AD 1800 in the New World) and the more distant record provided by studies of pollen, ice and sediments. In short, there is the exciting prospect of the construction of a climatic chronology of temperature and rainfall for much of the Northern Hemisphere over the last millennium that will be sufficiently accurate for us to evaluate the economic impact of the

*Held on 8-14 July, 1979 and organised by the Climatic Research Unit.

©Macmillan Journals Ltd 1979

fluctuations. As well as establishing our present climatic pattern quite firmly in the context of past changes, we can now say something about the range of alternative patterns of climate and weather we should be prepared for in the future. In particular, several papers reflected a significantly improved understanding of the nature of short-term climatic fluctuations, and the factors that distinguish them from long-term changes of the climatic pattern. The contributions from China were particularly welcome here because of the remarkably long and detailed run of records available.

The distinction between minor fluctuations and major changes may be arbitrary in terms of the mechanisms of climatic change, but it is important in comprehending their contrasting economic consequences. The ability of a rural economy, whether peasant or commercial, to absorb the shock of year-to-year changes in weather — or, especially, runs of adverse weather — is a critical factor in determining its economic success and its social harmony. Studies of climatic change and agricultural response strongly indicate the need for farming systems which will reduce the risks from uncertain weather by a spread of farming options. The irony is that improvements in technology and organisation enable us to respond more rapidly to drought in, for example, the Sahel or the US Great Plains; but, at the same time, they encourage farmers to adopt specialised and consequently risky farming systems that are more prone to suffer from climate changes. We can thus distinguish between the need for farming communities, especially in marginal areas, to be prepared and able to adapt to long-term changes of climate; and, on the other hand, the necessity of adopting farming systems which can absorb short-term climatic shocks without producing economic or social hardships.

These conclusions are drawn from several studies of marginal areas, where the nature of the climatic impact can more readily be interpreted. One of these is the cold marginal zone around the North Atlantic, whose reponse to climatic fluctuations has now been quite thoroughly researched. Analyses of options lost and gained by societies in Greenland, Iceland, Scotland and Norway were presented at the conference. The climatic constraint on agriculture in these areas is largely temperature; and, because this exhibits less variability than rainfall, any trend in its behaviour can be more readily detected, and suitable measures planned. The dry marginal zones in Africa, the Middle East and the US present a much greater problem, but there are encouraging signs of an increased understanding, particularly through the work of geographers based at Clark University, Massachusetts.

Moreover, we are now beginning to comprehend the enormous social and economic cost of climatic fluctuations. There are now quite precise measures of the relationship between Indian food grain production and monsoon reliability; of changes in the US regional and national house heating bill resulting from the postwar decline in winter temperatures; and of correlations between wheat production and weather patterns on the Soviet steppes. The return on predicting climatic fluctuations is, of course enormous, but it is unfortunately still not in prospect. In the meantime, our increased knowledge of the nature of the fluctuations and their impact should enable us to plan an improved ability to absorb the shocks and to adapt to the changes. In this sense, the Climate and History Conference was a milestone, for it marked the move from the pioneer phase of initial chronology construction to a secondary phase of impact evaluation; and for the pioneers who are witnessing this coming of age — Hermann Flohn, Hubert Lamb and Gordon Manley — this must have been an extraordinarily satisfying experience. □

Life and death before birth

by Mary Lindley

LIFE before birth is fraught with hazards, and for man at least they often seem to be too much for the fetus, leading to spontaneous abortion and stillbirth, known collectively as fetal wastage. Some of the factors controlling the fate of the fetus were aired recently at the annual symposium of the European Society of Human Genetics*.

The timing of some of the events of fetal wastage is beginning to become clear from studies of developing mice. The fate of XO mouse embryos is being investigated by P. S. Burgoyne (University of Edinburgh). Using female mice heterozygous for a large inversion of the X chromosome, he has obtained XX, XO and XY zygotes from XX mothers. He has found that when XO embryos from such mothers are cultured, they are often abnormal by the morula/blastocyst stage. Up to 11 days of gestation they are normal, but immediately after implantation some are resorbed. Burgoyne suggested that the preim-plantation abnormality leads to the postimplantation loss of XO embryos.

However, those embryos that survive the critical period seem to develop well, providing an intriguing parallel with the human situation. It has long been a puzzle that XO human fetuses have a very high rate of spontaneous abortion in the first three months of gestation, while those that are not lost then will progress quite well by the standards of embryos with chromosome abnormalities. Burgoyne has also compared mouse embryos from the XX mothers possessing the inversion with embryos from XO mothers and found a greater degree of retardation in the latter. He suggests that some maternal effect influences development in addition to the chromosome abnormalities produced in the offspring.

A. Gropp and colleagues (Institute for Pathology, Lübeck) have now looked at all nineteen trisomies of the mouse, using the breeding programme they designed for the purpose. As would be expected from what is known of the fate of abnormal human embryos, different trisomies survive for different times. Three critical periods of development can be recognised. Some of the embryos, including trisomies for chromosome 17, do not survive a first phase of organogenesis up to days 11 and 12 of gestation. Days 13 and 14 constitute the second critical period and trisomic fetuses surviving this far may have gross malformations, for example of the heart. These include trisomies 12, 14 and 16. The third critical period, days 15 to 18, seems to be associated with impaired placental function and oxygen supply. Some trisomic mice survive birth, but their subsequent life span is limited by general hypoplasia.

The human fetus is of course much less convenient for study, and although fetal wastage is known to be extensive, its full extent can only be estimated. According to A. Boué (Centre for the Study of Prenatal Biology, Paris) the accepted dogma is that 15% of all conceptions end in recognisable fetal wastage, while 31% survive to birth. The other 54% are presumed to be lost very early in gestation, but they cannot be detected.

E. Williamson and J. Miller (Southampton General Hospital) have come up with a value of about 40% early post-implantation loss in their prospective study of 195 women who were trying to conceive. By taking regular measurements of human choriogonadotropin in the urine, Williamson and Miller were able to recognise when pregnancies began and then follow their course, some ending in early loss and others proceeding further. It has still not been possible to recognise the time of fertilisation, and figures of the sort produced in this study require a generous measure of speculation. It seems that there is no substitute for specimens, but at the very early stages of gestation the problems of collection are too great at present.

Some of the earliest hazards, preceding even conception, arise during meiosis. This

©Macmillan Journals Ltd 1979

is still to a large extent a mysterious process, but clues to its dangers are beginning to emerge. A. G. Searle (MRC Radiobiology Unit, Harwell) pointed out that in male mice X-autosome translocations and a substantial number of autosomal reciprocal translocations (those with break points near one end of the chromosome) are particularly associated with a breakdown of meiosis, often due to failure of pairing. This leads to the impairment of spermatogenesis and almost complete male sterility. It is not clear why this should happen, and the puzzle is increased because similar translocations have no such drastic consequences in female mice.

During a session on sex determination A. Jost (College de France, Paris) pointed out some inadequacies in current thinking about the role of H-Y surface antigen in this process. The antigen has been widely discussed as the agent responsible for the differentiation of testes in mammals, in which the male is the heterogametic sex (XY), and of ovaries in birds and other vertebrates in which the female is the heterogametic sex (ZW). Jost pointed out that such a scheme is not compatible with the results of his own and earlier work on the development of freemartins. He said that the course of development is similar either when a female calf fetus is masculinised before birth in the presence of a male twin, or when a female axolotl or *Xenopus* is induced to become a male by having a testis grafted onto its ovary. In each case there is first a phase of no change, then profound retardation of ovarian development and finally, masculinisation, leading to complete sex reversal in the two amphibians. According to current theory, the role of H-Y in mammals is to masculinise rather than to suppress female organs, and Jost pointed out that this does not account for the early and prolonged ovarian inhibition. Also according to current theory, the heterogametic sex influences the homogametic sex, and this cannot explain why the heterogametic female amphibians were masculinised by the homogametic males. Some other explanatory scheme is needed, Jost said.

U. Wolf (University of Freiberg), the leading exponent of this work in Europe, explained his view of the role of H-Y antigen in development. From studies in his laboratory with gonads of rat and chicken, he concludes that H-Y acts as a signal inducing the undifferentiated gonad of the early embryo to become a testis in the XX/XY system or an ovary in the ZZ/ZW system. Thus the gonad begins to develop in the direction of one sex or the other according to whether H-Y is present or absent. Sex determination therefore involves control of the expression of a putative *H-Y* gene or genes specifying the production of H-Y antigen. Wolf believes that, although the *H-Y* gene is usually active only in the heterogametic sex, it is carried in the genome of both sexes. He said that its presence in the homogametic sex is demonstrated when embryonic chicken testis is treated with oestrogen and converted to ovotestis which will then produce H-Y antigen. This may offer comfort to those who never believed that the *H-Y* gene was on the Y chromosome, and perhaps encourage rumours that it is really on the X chromosome.

More insights into sex determination and the role of sex chromosomes are promised by the Scandinavian wood lemming — billed as 'The incredible *Myopus*' and as usual, enthusiastically championed by K. Fredga (University of Lund). Wild populations of this small rodent (*Myopus schisticolor*) contain unexpectedly large proportions of females, some of which produce only daughters. Breeding data are bearing out the hypothesis that an X-linked mutation (designated X*) prevents the expression of masculinity in the presence of a Y chromosome, so that X*Y, as well as XX and X*X will be phenotypically female. Fredga said that the chromosomes X and X* can be distinguished by their banding patterns. Most X*Y females produce only daughters because a unique form of non-disjunction gives rise only to eggs carrying the X* chromosome. A consequence of the failure of this mechanism is the production of an unusually high proportion of offspring with abnormal sex chromosome constitutions. Fredga and his colleagues in Lübeck, A. Gropp and H. Winking, have bred X*YY fertile females, X*XY sterile males and an X*XY true hermaphrodite with an ovary on one side of its body and a testis on the other. They believe this indicates that the normal X chromosome is necessary for male development, with at least two genes involved, possibly one structural and the other regulatory. Fredga suggested that the development of X*XY individuals is influenced by the pattern of X chromosome inactivation. Thus in the hermaphrodite, inactivation of the normal X would have resulted in the development of an ovary, while inactivation of X* would have resulted in a testis. Further news of *Myopus* will be awaited eagerly. □

Mars volatiles

from C. T. Pillinger

IT is now almost 8 years since Mariner 9 went into orbit around Mars and found the planet shrouded by a gigantic dust storm to such an extent that only the very largest topographical features were visible. The storm abated and no doubt everyone remembers those tremendous first pictures of our nearest planetary neighbour. Later, in 1976, two Viking spacecraft, both soft landers and orbiters, continued the exploration of Mars. During the primary mission (June to November) little or no dust activity was observed. However, the scientific groups involved continued to monitor their instruments throughout the extended mission and data for an entire Martian year (approximately two Earth years) have been obtained. In that time 16 local and two global (although not as intense as the 1971 example) storms were observed. 'Mars Volatiles (and Meteorology and Dust)' (*J. Geophys. Res.* **84**, 136, 2793-3007; 1979) is a compilation of 16 papers by members of the Viking Volatile and Meteorology Working Group dealing with the results of the extended mission. Although various atmospheric problems are considered, dust and dust storms provide a common thread. As the working group ceased to have any official standing long ago, its members should be commended for the effort which must have gone into internal editing and cross-referencing so that readers are presented with a continuous story. All the papers are interesting and informative even to a casual reader looking for some general knowledge about Mars. The complete volume or high quality reprints of any of the papers may be obtained from the American Geophysical Union.

It is not easy to summarise the cumulative efforts of such a diverse study but some of the points of most general intest might be as follows. (All references following are to the volume cited above). It appears that dust storms occur predominantly when Mars is near perihelion and originate mainly in the southern hemisphere possibly near the ice cap (Briggs *et al.*) Local storms are up to 8 km high and have abrupt tops (Peterfreund & Kieffer). Surface pressure oscillations indicate that thermally driven global atmospheric tides are involved with the major storms (Leory & Zirek). Perhaps not surprisingly, measurements of wind, surface and atmospheric temperature and pressure reveal that the arrival of storms is accompanied by significant changes in these parameters (Ryan *et al.*; Martin & Kieffer). Infrared thermal mapping may be able to distinguish ground fogs and water ice clouds from dust and to provide information about the structure of the lower atmosphere (Hunt). The observation that water vapour is uniformly distributed in the atmosphere explains the lack of predicted early morning diffuse fogs. Thus, water is not frozen out at night and

ICE on Mars again — This high-resolution photo of the surface of Mars was taken by Viking Lander 2 at its Utopia Planitia landing site on May 18, 1979, and relayed to Earth by Orbiter 1 on June 7. It shows a thin coating of water ice on the rocks and soil. The time the frost appeared corresponds almost exactly with the buildup of frost one Martian year (23 Earth months) ago. Then it remained on the surface for about 100 days. It is thought that dust particles in the atmosphere pick up bits of solid water. That combination is not heavy enough to settle to the ground. But carbon dioxide, which makes up 95% of the Martian atmosphere, freezes and adheres to the particles and they become heavy enough to sink. Warmed by the Sun, the surface evaporates the carbon dioxide and returns it to the atmosphere, leaving behind the water and dust. The ice seen in this picture, like that which formed one Martian year ago, is extremely thin, perhaps no more than one-thousandth of an inch thick.

exchanged between the surface and the atmosphere on a daily basis (Davies). The global and seasonal distribution of water vapour is consistent with a 10 cm to 1 m reservoir of H_2O in the regolith at latitudes above 40°. An asymmetrical transfer of water from south to north at a deposition rate of a few milligrams per square centimetre occurs possibly due to the propagation of storms in the south (Farmer and Doms). The spring–summer recession of the south pole observed by the Viking 2 orbiter was slower than previously reported by Mariner and Earth-based telescopes. Occurrence of a dust storm at the appropriate time might have been responsible (James *et al.*). Seasonal variations of up to 26% in atmospheric pressure are caused by evaporation of the ice caps — approximately 7.9×10^{12} tonnes or a 23 cm thick layer needs to be exchanged (Hess *et al.*). The temperature of the south polar cap in winter is significantly below the expected 148 K. One explanation is that there is a reduction of CO_2 in the atmosphere and a lowering of mean molecular weight near the surface (Hess). Wind speed and direction, pressure, temperature and optical depth measurements indicate the existence of low and high pressure 'weather' systems in the atmosphere (Tillman *et al.*). Optical depth studies also provide information about the shape and imaginary refractive index of the dust; the cross sectional weighted mean radius is estimated to be around 2.5 μm. At the moment, water ice and CO_2 are being preferentially deposited in the north polar regions because of scavenging by the dust. Equatorial and mid latitude regions are probably being eroded at a rate around 7 m per 10^6 yr; it may take 10^5 yr to produce the individual strata observable at the poles (Pollack *et al.*). Thus, cyclic variations in direction over geological time have led to sedimentary deposits of millions of cubic kilometres under both poles as testimony to the effects of dust storms. Parallel undulations of period a few kilometres and height a few tens of metres observed near north polar surfaces may be the intermediate topographic features (Cutts *et al.*).

Perhaps the only unrelated, but nevertheless interesting paper (Carr), describes the formation of the chaotic terrain, thought to be Martian flood features, formed by the release of water from confined aquifers. □

New routes to polypeptide hormones

by Peter Newmark

THE production of polypeptide hormones has, until very recently, started either in the slaughter-house/mortuary or on the solid phase beads of the organic chemist. But at a recent meeting* it was clear that the knife and the spatula are yielding to the restriction enzyme, although not without a struggle.

A particularly elegant example of the bacterial route to the production of a human hormone was recounted by D. V. Goeddel (Genentech, San Francisco). Since the synthesis of the complete nucleotide sequence corresponding to the 191 amino acid human growth hormone (hGH) would have been a monumental task and since the use of DNA copied from natural messenger RNA and then converted to double-stranded form (ds cDNA) would have coded for the precursor to hGH which bacteria would not be able to process to the mature hormone, the following approach was taken. First ds cDNA for hGH was cloned and treated with restriction enzymes to give a DNA sequence corresponding to all but the first 23 amino acids of the hormone. Then the synthetic polynucleotide corresponding to amino acids 1-23 and preceded by an ATG initiation codon was cloned. Finally the two fragments were ligated and cloned 'behind' a pair of *lac* promoters and a ribosome binding site.

*The 12th Annual Miles Symposium on Polypeptide Hormones was held in Baltimore, 11-13 July, 1979.

0028-0836/79/340637-01$01.00

©Macmillan Journals Ltd 1979

This led to a considerable yield of 186,000 copies of radioimmunoassayable hGH activity per *E. coli* cell (2.4 $\mu g\ ml^{-1}$). Furthermore, and as planned, the product was of about the correct molecular size, not being fused to a plasmid-determined protein as has been the case in most previous approaches to the bacterial production of hormones (see for example Martial *et al. Science* **205**, 602; 1979).

Given Genentech's efforts and their plans to market hGH in collaboration with Kabi, it was surprising to hear doubts expressed that more hGH is really needed. In the USA at least, said S. Raiti (National Pituitary Agency), although there were theoretical grounds for believing that several thousand untreated patients existed, in practice the medical demand for hGH was readily met by hGH isolated from cadaveric pituitaries. On the other hand he conceded that lashings of the hormone would allow proper trials of its mooted efficacy on burns, non-healing fractures, ulcers and haemopoiesis.

As yet, however, not even the biological activity of the presumed hGH has been tested. Indeed it remains to be shown that any bacterially-produced hormone has proper biological activity although Lydia Villa-Komaroff (University of Massachusetts, Worcester) reported that the substance released by trypsin treatment of fused β-lactamase–insulin produced by bacteria was somewhat active in a rat fat pad bioassay.

Another polypeptide (?hormone) that is attracting the attention of genetic manipulators is interferon. One only has to read *Omni* these days to discover that interferon is the great white hope of cancer therapy. The problem with both *Omni* and interferon is to separate science fiction from fact. For interferon that problem will only be overcome when it is available in sufficient quantities and in pure enough form for proper trials to be carried out. As yet the few, if encouraging, results that have emerged from clinical tests have relied on interferon that is less than 10% pure.

Greater purity is one of the main aims of both S. Pestka (Roche Institute of Molecular Biology, New Jersey) who is purifying interferon from chronic myeloid leukaemia serum and of C.B. Anfinsen (National Institutes of Health) who will soon be growing 1,000 litres of human lymphoblastoid cells as his source. Purity is important not only for clinical trials but for the determination of interferons's structure. So far it is thought to be a polypeptide of about 154 amino acids. The polypeptide is associated with carbohydrate components which, however, are not essential for activity. It is said (by others) that both at NIH and at Dupont the N-terminal amino acid sequence of interferon has been determined. If true that may give the genetic manipulators their entrée. For with a synthetic polynucleotide complementary to the N-terminal amino acid sequence it may be possible to fish out pure messenger RNA for interferon to make cDNA for subsequent cloning.

Does the bacterial approach leave anything for the synthetic peptide chemist to do? Certainly! In the first place chemical synthesis still makes much sense for the smaller peptides, 'smaller' being less than 20 to 75 amino acids, depending on whose opinion one takes. It should however be noted that even for such a small peptide as the 14-amino acid somatostatin the bacterial route of production may be commercially viable; otherwise why will it become Genentech's first marketed chemical (for research purposes only) by the end of this year? Second, chemical synthesis is inherently 'cleaner' and has been considerably improved by the advent of continuous flow techniques with the prospect of real time monitoring of the products (B. W. Erickson, Rockefeller University). Third, chemical synthesis is well suited to the production of labelled peptides and peptide analogues. That is particularly the case when the analogues contain either modified or D-amino acids.

The synthetic peptide chemists have had, for example, considerable success in producing potent agonists and antagonists of the 10-amino acid peptide, luteinising-hormone-releasing-hormone (LHRH). Chiefly by the substitution of a D-amino acid at the sixth of the ten positions and by N-terminal changes, it has been possible to produce 'super LHRHs' with more than a hundredfold the potency of the natural hormone but also with paradoxical antifertility effects (see for example Ying & Guillemin, *Nature* **280**, 593; 1979). Considerable progress has also been made in producing analogues that are LHRH antagonists. The most active antagonists described by D. H. Coy (Tulane University, New Orleans) have para-halogenated D-phenylalanine at position 2 and acylated D-phenylalanine at position 1. Those substitutions together with a D-tryptophan at position 6 result in an antagonist that blocks ovulation at 0.03 mg per rat. Three years ago the best antagonists were 30-fold less potent.

The peptide chemists have had less success so far in improving on those thymic hormones whose structure has been determined, thymopoietin and FTS ('facteur thymique serique'). Thymopoietin is 49 amino acids long but a constituent pentapeptide has the biological activities of the full molecule (G. Goldstein, Ortho Pharmaceutical Co.). FTS is a nonapeptide first isolated from pig serum, now from human serum, and shown also to be present in thymic epithelium (J. F. Bach, Hôpital Necker, Paris).

Another serum peptide with effects on T cells is likely to be a tetrapeptide, possibly with a methylated amino acid at the N-terminus (A. Astaldi, Netherlands Red Cross Blood Transfusion Service). Ironically the only clinical trials that were reported involved either the relatively crude 'thymosin fraction V' of A. W. Goldstein (George Washington University, Washington) or the unsequenced 'THF' polypeptide of N. Trainin (Weizmann Institute). Thymosin fraction V has recently proved effective in prolonging the survival of patients with oat cell carcinoma. And THF has induced a remarkable recovery in immunosuppressed children with lymphoproliferative diseases who had developed infections. The basis of these clinical successes, the cellular or molecular effects of thymic hormones and the relationship of the various contenders for that title remain mysterious.

The testing and production of polypeptide hormones is clearly a very competitive business. It will not be unprecedented if the clinical optimism evident at this stage has to be moderated when larger scale trials can be completed. Meanwhile amongst the genetic manipulators the perceived returns have led them to adopt Madison Avenue tactics. A sobering-up period will doubtless follow when the products have to be shown to be suited to clinical use. Meanwhile many claims are made to the effect that bacterial production is both cheaper and easier than present techniques. It will be interesting to see whether the eventual price as well as the availability of the hormones reflects current optimism. □

A hundred years ago

But there is, perhaps, nothing which shows more strikingly the identity of the protoplasm in plants and animals, and the absence of any deep-pervading difference between the life of the animal and that of the plant, than the fact that plants may be placed, just like animals, under the influence of anaesthetics.

We owe to Claude Bernard a series of interesting and most instructive experiments on the action of ether and chloroform on plants. He exposed to the vapour of ether a healthy and vigorous sensitive plant, by confining it under a bell-glass into which he introduced a sponge filled with ether. At the end of half an hour the plant was in a state of anaesthesia, all its leaflets remained fully extended, but they showed no tendency to shrink when touched. It was then withdrawn from the influence of the ether, when it gradually recovered its irritability, and finally responded, as before, to the touch.

It is obvious that the irritability of the protoplasm was here arrested by the anaesthetic, so that the plant became unable to give a response to the action of an external stimulus.

Nuclear vibrations

G. F. Bertsch
Michigan State University, East Lansing, Michigan 48824

Three types of nuclear vibrations have been observed in which a large fraction of the nucleons participate. There is a satisfactory explanation for the vibrational frequencies but not for the damping rates.

NUCLEI, like more familiar mechanical systems, can undergo simple vibratory motions. One mode of motion, in which protons move together in one direction while the neutrons simultaneously move in the opposite direction, has been known for 30 years. In the past decade, several new vibrational modes have been discovered. Our theoretical understanding of the nuclear motion has also considerably advanced. Although the most refined descriptions of the motion require a quantum many-body theory, the main features of the vibrations can be understood using classical physics. The motion of an extended body is described by a field of vectors which give the velocity of the medium at each point. Figure 1 shows the velocity fields for three types of vibration: monopole, dipole and quadrupole. These three modes are exhibited by nuclei as so-called 'giant vibrations', in which a large fraction of the nucleons participate in the motion. In both the monopole and quadrupole modes, all the nucleons move coherently in a direction which depends on their position in the nucleus. In the dipole motion, as mentioned above, protons and neutrons move in opposite directions.

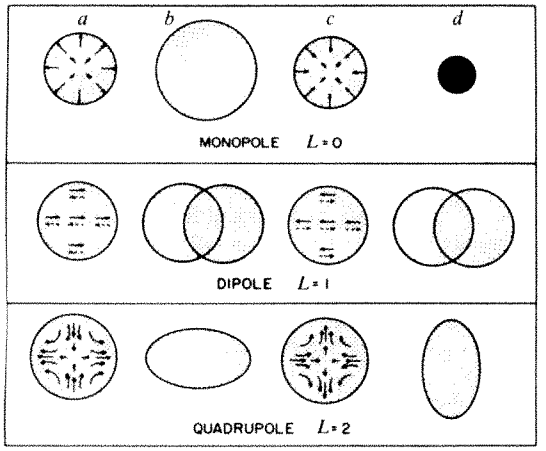

Fig. 1 The cycle of oscillation for simple vibrations. The velocity field at the moment when the nucleus passes through the equilibrium shape is shown in *a* and *c*. The shape at maximum distortion is shown in *b* and *d*. For the dipole, the neutrons and protons move in opposite directions. For other modes, the neutrons move with protons.

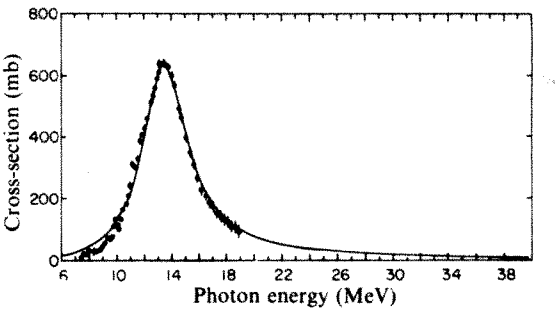

Fig. 2 The giant dipole resonance in ^{208}Pb, as observed by the photon reaction cross section (ref. 3, Fig. 32). The points are the experimental data, and the curve is the lorentzian function.

Dipole vibration

The first nuclear vibration to be observed, the giant dipole, was found in measurements of photon absorption. The reaction cross-section is enhanced by resonance when the photon frequency matches the vibrational frequency. The first indications of the giant dipole resonance were obtained before photon beams with a broad energy range were available. Bothe and Gentner in 1937 had a source of 14 MeV photons and they measured the radioactivity produced in a variety of targets[1]. The cross-sections varied considerably from target to target, indicating that there was a resonant absorption in some of the targets. By the mid-1940s, electron accelerators became available which produced bremsstrahlung photon beams of sufficient energy to observe the resonance. The improved data[2] showed that the absorption was concentrated in a resonance, the frequency of which varied systematically with the size of the nucleus.

One problem with these measurements is that the bremsstrahlung beam is broadly distributed in energy, so that the measurement for a particular energy required careful subtraction techniques. Currently, these experiments are done with photons that are produced by annihilation of positron, and are therefore monoenergetic. An example of the data now available[3] with this improved technique is shown in Fig. 2. The points are experimental data, and the curve is the lorentzian distribution,

$$\sigma(E)=\frac{\sigma_m}{1+[(E^2-E_m^2)^2/E^2\Gamma^2]}$$

This formula has three parameters: a maximum strength σ_m, a centre frequency E_m, and a damping width Γ, which are adjusted to fit the data. For the heavier nuclei, the frequency depends on nuclear mass number A roughly as $\hbar\omega = 80/A^{1/3}$ MeV. The damping width is 4–5 MeV.

The spatial structure of the vibration, with protons moving against neutrons, is inferred indirectly from the data. Photons at the frequencies of interest have a long wavelength (~100 fm) on the scale of nuclear dimensions $R \sim 1.2\,A^{1/3} \sim 3$–$8$ fm. With a long wavelength, the force field is quite uniform and the photons cannot excite other kinds of motion besides the uniform displacement of protons against neutrons. Thus, as is the case with optical photons interacting with atoms, all but a negligible fraction of the cross-section is due to dipolar motion. It is useful to compare the magnitude of the cross-section with a theoretical limit known as a sum rule. The Thomas–Reiche–Kuhn sum rule for the absorption is given by[4]

$$\int_0^\infty \sigma(\omega)\,\mathrm{d}\omega = \frac{2\pi^2 e^2}{Mc}\,\frac{NZ}{A}$$

where M is the mass of a nucleon, and N, Z are the neutron and proton numbers. The dipole vibration will satisfy this sum rule only if all the protons move coherently with a uniform translation. In the example shown in Fig. 2, the experimental absorption strength from the lorentzian fit is 3,000 MeV mb, which is just the limit from the sum rule. Thus, the motion in the dipole vibration seems to be completely coherent. This conclusion is modified by the presence of charged mesons.[5]

Quadrupole and monopole vibrations

As mentioned above, wavelengths shorter than can be provided by photons are needed to excite the monopole and quadrupole vibrations. The quantum relationship between momentum and wavelength, $p = h/\lambda$, implies that modes with more complex spatial structure can be excited only if enough momentum is given to the nucleus at the same time. This condition can be met by the inelastic scattering of massive projectiles. The first published experiments exhibiting a new vibration were done in 1957 with inelastic proton scattering at 180 MeV (ref. 6). Figure 3 shows these data; a distinct bump is visible at 18 MeV excitation. However, the significance of this bump was not realised until in 1971, when Bertrand and coworkers[7] found the bump in their own data taken at lower energies and concluded that it was the quadrupole vibration of Fig. 1. Others also saw the vibration in electron scattering[8], and offered a quadrupole vibration as one of the possible explanations.

The main evidence that the bump might be a quadrupole vibration was the angular distribution of the scattering cross-section. Each multipolarity has a characteristic shape to the angular distribution, which can be calculated by the Schrödinger equation for the projectile wavefunction. If the wavelength of the projectile is short compared to the dimensions of the target,

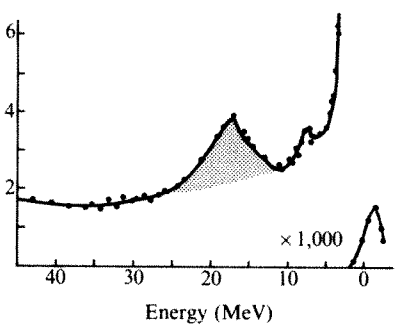

Fig. 3 Inelastic proton scattering spectrum for 180 MeV protons on a Ca target (ref. 5, Fig. 2). The stippled bump is the quadrupole vibration. The rise in cross-section towards zero excitation energy is the elastic scattering.

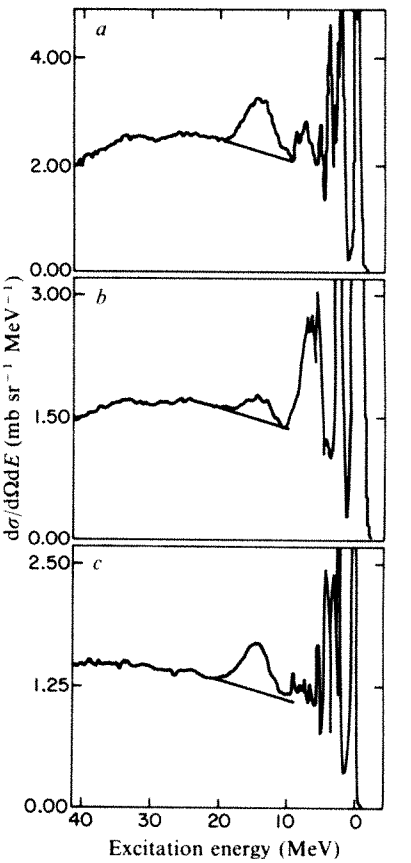

Fig. 4 Inelastic α-particle scattering on ^{90}Zr, taken at three different angles. *a*, $\theta_{lab} = 17.5°$; *b*, $\theta_{lab} = 20.5°$; *c*, $\theta_{lab} = 22.5°$. The giant quadrupole is prominent at 17.5° and 22.5°, but is much reduced at 20.5° (ref. 9).

the angular distribution peaks at an angle given roughly by $\theta = L/\lambda R$, where L is the multipolarity of the excitation and R is the nuclear radius. At larger angles, the cross-section is oscillatory, with interference from the projectile passing opposite sides of the nucleus. Some recent data with angular dependence is shown in Fig. 4[9].

The reaction is induced by α particles scattering on the nucleus ^{90}Zr. A prominent peak is seen at angles of 17.5° and 22.5°, but much reduced at 20.5°. This behaviour is only consistent with the predicted angular distributions for quadrupole or monopole vibrations. To decide between monopole and quadrupole, one must either look at smaller angles, or argue on the basis of the absolute strength of the peak.

As in photon absorption, sum rules can be used to analyse the absolute strength. However, the strength of the interaction for projectiles such as protons and α particles is not as well known *a priori* as it is for electromagnetic probes. To avoid this problem, the interaction between specific projectiles and target nucleons is adjusted by fitting the elastic scattering data. The interaction determined in this way describes inelastic transition quite well, and for many cases can be checked independently by its electromagnetic properties[10].

Defining V as the potential field of the scattering projectile on the target, the inelastic scattering sum rule reads

$$\sum_f (E_f - E_i)\langle i|V|f\rangle^2 = \int \mathrm{d}^3 r n_0(r)\,\frac{(\vec{\nabla}V)^2}{2m}$$

where n_0 is the density of nucleons in the ground state and the excited states are labelled by f. This sum rule is easily understood in classical terms. The left-hand side is the average energy given to the nucleus by the collision. On the right-hand side, $\vec{\nabla}V(r)$ is the impulse given to a target nucleon at position r. Thus $(\vec{\nabla}V(r))^2/2m$ is the average kinetic energy given to a nucleon at r, and the integral is the average total energy given to

the nucleus. Since the integral involves only the ground state density, it can be reliably computed and compared with the actual strength of a given vibrational excitation. The peak in Fig. 4 has about 75% of the strength for a quadrupole vibration; if it were monopole the sum rule would be exceeded.

By now the systematic behaviour of the quadrupole vibration has been thoroughly studied[11]. The mean frequency varies with mass number as $\omega \sim 63/A^{1/3}$ MeV/$\hbar$. The width varies from 8 MeV in light nuclei to 3 MeV in heavy nuclei, with dips at magic nuclei.

In the past two years, experiments have been done at smaller angles, where the monopole and quadrupole have different behaviour. Inelastic scattering at 0° should favour the monopole vibration. The physics behind this is shown in Fig. 5 which shows a projectile wave enveloping a nucleus. The attractive interaction between the projectile and the target pulls the nucleus out along the equatorial region. This outwards motion can be resolved into a major monopole component and a minor quadrupole component. All the wavelets from the projectile will interfere coherently at 0° scattering angle. So, like the Poisson spot seen in optical diffraction around spheres, the scattering will show a pronounced peak at 0°.

The quantum calculations of the scattering support this picture: Fig. 6 shows calculations comparing the angular distributions of monopole and quadrupole at the most forward angles[36]. These calculations treat the excitation of the vibration in the Born approximation, and use the solution of the Schrödinger equation in an optical potential for the projectile wavefunction. The sharp rise of the monpole near 0° is evident.

As the experiments have progressed to smaller angles with shorter wavelength projectiles, evidence has accumulated for a monopole vibration at a frequency slightly higher than the quadrupole. Figure 7 shows recent data (D. Youngblood, personal communication) for 0° inelastic α scattering. The centroid of the peak is at

$$\omega \sim 80/A^{1/3}\ (\mathrm{MeV}/\hbar)$$

Fortuitously, this is the same frequency as the dipole mode. The damping width of the vibration is about the same as for the quadrupole.

Theory

Paralleling the experimental developments, there have been considerable advances in the theory of the vibrations. The general theory, derived from many-body quantum mechanics in the 1950s, is known as RPA (random phase approximation). This theory was originally applied to nuclei[12,13] in models which used an oversimplified description of the wavefunction. These models were instructive in exhibiting qualitative trends for the vibrational frequencies but they had severe deficiencies. The sum rules were not satisfied. The interaction between particles was unrealistic, and in many cases had to be adjusted to fit observed vibrational properties. In the past decade it has become possible to do the theory properly. The availability of

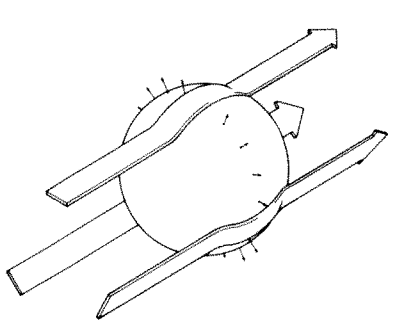

Fig. 5 A projectile wave, depicted with the broad arrows, envelops a nucleus and induces the transverse motion of the nucleus, shown with the small arrows. This motion resolves into a combination of monopole and quadrupole vibrations.

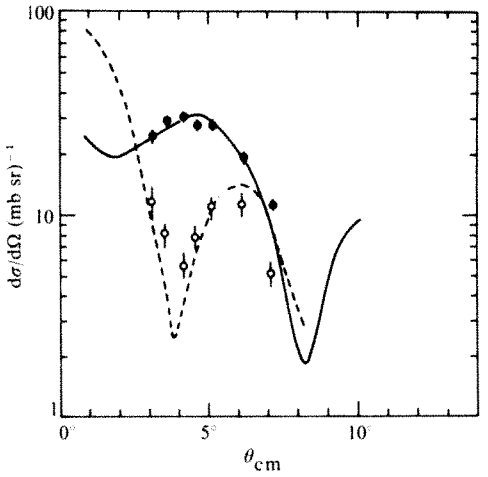

Fig. 6 Angular distribution for inelastic α scattering on ^{208}Pb (ref. 36). The solid line is the theoretical distribution for exciting a quadrupole vibration $E_x = 11.0$ MeV; $L = 2$, and the dashed line is the theoretical distribution for the monopole $E_x = 13.7$ MeV; $L = 0$. Points are data extracted by fitting the peaks like those in Fig. 4.

medium-sized computers means that the description of the wavefunction can be kept sufficiently general. In a configuration representation, the number of configurations for a heavy nucleus is typically several hundred. An example of an RPA calculation of the photon absorption strength is shown in Fig. 8[14]. The other key to a quantitative theory is the use of the same interaction hamiltonian to describe the vibrations as is used for the Hartree–Fock ground state. The important property of the interaction is that it contains a short range attraction which diminishes as the density increases. A simple parameterisation of the hamiltonian introduced by Skyrme has the form,

$$H = \sum_i \frac{p_i^2}{2m} + \sum_{i<j} v(n_0, \mathbf{p}_i, \mathbf{p}_j)\, \delta(r_i - r_j)$$

where v is a polynomial function of density $n_0(r)$ and momentum $\mathbf{p}_i$. Such a hamiltonian can be determined by fitting ground-state sizes and binding energies[16]. More fundamental theories of the interaction, based on the free nucleon–nucleon potential, can be reduced to the Skyrme form.[17] With the zero-range interaction, the Hartree–Fock ground states of nuclei are easily computed, as is the RPA response. With the largest computers, it is feasible to remove the restriction to zero-range interactions in the hamiltonian, and the most sophisticated RPA calculations are based on a more general parametrisation[18]. Using a hamiltonian consistent with ground state properties, the RPA gives an excellent description of the vibrations without any adjusted parameters[19]. The sum rules are automatically satisfied. The giant vibrations, with the exception of the monopole, are found at the proper frequency. The frequencies of low vibrations are generally reproduced to 10%. Figure 9 compares the theoretical[20] and experimental[19] density fluctuation in a low-frequency vibration of ^{208}Pb. Note that the density fluctuation is strongest at a radius ~7 fm, which is at the nuclear surface.

The RPA can be simplified to algebraic formulae when the vibration exhausts the sum rule. These formulae are analogous to the classical formula for a vibrational frequency ω in terms of a mass M and spring constant k, $\omega^2 = k/M$. Before the RPA theory was known, classical models were proposed *ad hoc*. In the case of the dipole vibration, the mass is simply the mass of the protons and neutrons. The restoring force is due to the change in potential energy when the protons and neutrons are displaced with respect to each other. The dipole frequency was first calculated along these lines by Migdal in 1944 (ref. 22; see also refs 23. 24). The dipole motion in Fig. 1 physically separates neutrons from protons in the surface region: Migdal modified

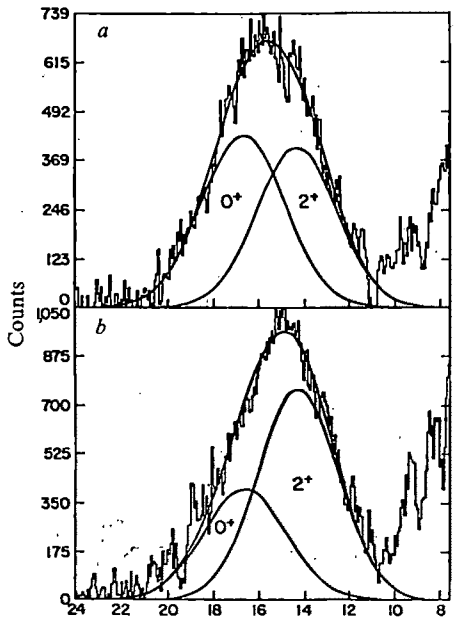

Fig. 7 Comparison of the α scattering at *a*, 0°; and *b*, 4°. The peak is shifted upward in energy at 0°, due to the relative enhancement of the monopole at the forward angle.

the velocity fields to keep the particles together at the surface. The predicted frequency is then found to be

$$\omega \sim \left(\frac{4.3 b_s}{MR^2}\right)^{1/2} \sim 80/A^{1/3}\ (\mathrm{MeV}/\hbar) \qquad (1)$$

where $b_s = 50$ MeV is the symmetry energy of nuclear binding. The reduction of RPA yields a formula that contains additional factors arising from mesons and from a more accurate description of the velocity field[25,26]. These corrections tend to cancel, and equation (1) is in excellent agreement with the empirical vibration frequencies of the heavier nuclei.

Migdal[22] and others[27] also tried to calculate the quadrupole vibrational frequency, but in this case the classical ideas were simply wrong. It was assumed that the surface tension of the nuclear surface provided the restoring force to the spherical shape. The general formula for liquid drop vibrations was derived by Rayleigh, and is

$$\omega^2 = \frac{\sigma n_0}{MR^3} L(L-1)(L+2)$$

where σ is the surface tension. The formula can be evaluated using the nuclear surface tension derived from binding energy systematics. The predicted frequency is found to be ~2 MeV for heavy nuclei, which is much too low[27]. However, as mentioned above, RPA calculations do predict the quadrupole vibration at the correct frequency. In fact, on the basis of such calculations Mottelson in the 1960s urged a search for the mode.

The reason why the classical calculation fails is that the main element in the restoring force is neglected. There is a resistance to shearing motion in any Fermi system caused by the complex spatial structure of the many-Fermion wavefunction. It turns out that the elastic shear modulus is proportional to the quantum kinetic energy of the particles. The proper formula for the vibrational frequency based on this restoring force is

$$\omega^2 = \frac{2\langle T\rangle}{M\langle r^2\rangle} \qquad (2)$$

Here $\langle r^2\rangle$ is the mean square radius of the ground state, and $\langle T\rangle$ is the average kinetic energy per particle in the nucleus. Note that this formula, unlike the liquid drop formula, has the correct $A^{-1/3}$ dependence of frequency on mass number because $\langle r^2\rangle \sim A^{2/3}$. When a simple estimate is made of the kinetic energy per particle, for example, with the Fermi gas model or harmonic oscillator model, the predicted frequency from equation (2) agrees with the empirical model to better than 10%. As in the case of the dipole, equation (2) is somewhat oversimplified, since some of the subtler effects of the nuclear interactions are neglected[28].

We now consider the theory of the most recently discovered giant vibration, the monopole. The frequency of the monopole is especially interesting because it is directly related to the compressibility of nuclear matter. The compressibility is a fundamental property of the medium, but up to now there has been no way to measure it. There have been many calculations of nuclear compressibility beginning in the early 1940s, before the nuclear interaction was very well known. Techniques of calculations have since become very sophisiticated, but we do not yet have a satisfactory understanding of the equilibrium density of nuclear matter[29]. More detailed properties of the nuclear medium, such as its compressibility, are correspondingly more difficult to calculate. However, the existing calculations should serve as a guideline. Predicted values for the compressibility are in the range

$$k = V^2 \frac{\partial^2 E}{\partial V^2} = 2.5\text{–}5\ (\mathrm{MeV\,fm^{-3}})$$

with the higher number being more recent. The classical relationship between the radial vibration frequency and the compressibility of a liquid drop is $\omega^2 = \pi^2(k/Mn_0R^2)$. Applying this formula to finding k from the empirical ω, the compressibility of nuclear matter turns out to be $k \approx 3.5$ MeV fm^{-3}. Having fixed the compressibility coefficient with the information from the monopole, it will now be possible to make more reliable calculations of other phenomena involving high-density nuclear matter. This includes high-energy heavy-ion collisions and the formation of neutron stars.

Damping

The damping of the nuclear vibrations is not well understood, theoretically or experimentally. There are two possible mechanisms for the damping. The vibration may disappear by emitting particles, which could be called evaporation; or the motion may mix with the more complex degrees of freedom in the many body system, which is analogous to friction. This complex state would eventually decay according to statistical considerations, which generally emphasise low-energy neutron emission. The measurement of decays of giant vibrations is a very active area of research. Some published experiments in the heavier nuclei claim that the decays are inconsistent with the statistical picture[30,31]. On the theoretical side, the damping by particle emission is found to be unimportant except in light nuclei. In RPA, the damping rate due to nucleon emission can be

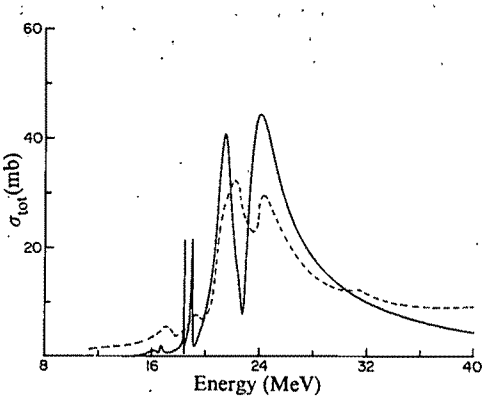

Fig. 8 The photon absorption strength of ^{16}O in the RPA theory (solid line)[14], compared with experiment (dashed line). The resonance is split into five components by the shell structure, and has a width due to the decay by nucleon emission.

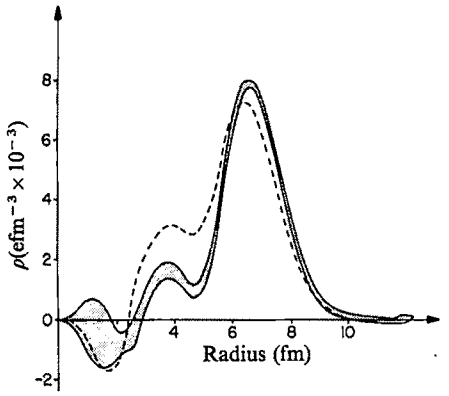

Fig. 9 The transition charge density $\langle 3^-|\rho|0^+\rangle$ for the lowest $L=3$ state in ^{208}Pb. The experimental density[20] (hatched area) is measured by a Fourier–Bessel transform of the electron scattering form factor. The theoretical density[19] is the result of an RPA calculation (dashed line), using a large basis for the wavefunction but a simple interaction.

calculated directly[14,15]. The rate of emission of heavier particles, such as α particles, is more difficult to calculate but is also estimated to be small.

Nevertheless, the study of emitted particles has provided a useful tool for studying the vibrations. By examining a particular final transition, the emitted particle can be forced to carry away the entire angular momentum of the vibration. If a coordinate system is chosen in which there is no angular momentum about the z axis, the angular distribution of the particle then follows a Legendre function, $N(\theta) \simeq (P_L(\theta))^2$.

Such a measurement was made for the giant quadrupole of ^{16}O, decaying by α-particle emission to the states in ^{12}C (ref. 32). The angular distribution for the ground ' tate transition, which satisfies the above condition, is shown ı Fig. 10. The data exhibit a peak at 0° of the right width to be described by $[P_2(\theta)]^2$. However, unlike the Legendre function, the data is not symmetric about 90°. This means there must be coherent mixtures of angular momenta. The fact that the background interferes with the decay of the vibration is not really unexpected. In the classical limit nucleon emission can take place by the projectile's knocking out a nucleon in the direction of the momentum transfer. The quantum description of this process requires intereference from many angular momenta. It remains to be seen what theory predicts about how much interference is required.

The other form of damping is caused by mixing with more complicated modes of motion. A simple example of this is the behaviour of the dipole state in a deformed nucleus. A vibration in an arbitrary direction resolves into vibrations along the principal axes with different frequencies. This is seen in Fig. 11, showing the dipole strength for an ellipsoidal nucleus.

The lineshape can be well described as the sum of two lorentzian curves. The lower frequency and higher frequency components correspond to the vibration along the major and minor axes respectively. The difference in frequencies agrees well with the R dependence in equation (1). Because there are two minor axes, the upper peak is predicted to have twice the strength which is found to be the case empirically. For the quadrupole vibration, there are three distinct frequencies instead of two, and the overall splitting is smaller because the motion has components along both principal axes. Consequently, for the quadrupole the deformation splitting is much more difficult to see.

The major source of damping is mixing with the statistical degrees of freedom of the many body system. In principle, this could be calculated from the shell model representation of nuclear wavefunctions, and several calculations along such lines have been reported[33,34]. However, these calculations are not transparent, and it is more instructive to ask how the damping of the vibrations compares with damping of other kinds of motion.

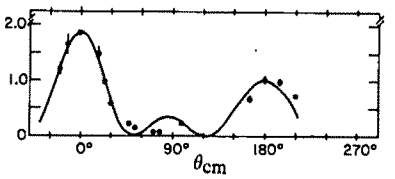

Fig. 10 Angular distribution of decay α particles following excitation of ^{16}O in the giant quadrupole region[32]. The 0° axis is along the momentum transfer direction. The probability distribution peaks in this direction, and also has a smaller peak in the opposite direction. $E_x = 17.9$–19.2 MeV.

The simplest motion is that of a single nucleon across the nucleus. This is described quantum mechanically with an optical potential, and the finite lifetime of the nucleon τ is related to the imaginary part of the optical potential $\langle W\rangle$ by $\hbar/\tau = 2\langle W\rangle$. Optical potentials can be inferred from elastic scattering of low energy nucleons and from the capture of neutrons. The spreading of the single-particle strength can also be seen directly in the reactions in which a nucleon is transferred between the projectile and the target. These methods yield a damping width for nucleons close to the particle emission threshold of about $\hbar/\tau \approx 5$ MeV.

A naive model of the vibrational damping can then be constructed, utilising the representation of the wavefunction in terms of single-particle wavefunctions. The vibration is a superposition of one particle above the Fermi level together with a hole in the Fermi sea. Each of these should have a single particle lifetime so the total damping width would be twice that, hence $\hbar/\tau \approx 10$ MeV.

This estimate ignores a coherence in the vibrational motion: the fact that all of the particles are moving together inhibits the coupling to other degrees of freedom. This coherence is well-known in other quantum systems. For example, in metals the plasmon vibration might only be damped by 1 eV while an electron at the same energy has a damping many times larger. In fact, the detailed calculations of nuclear vibrational damping do show this quenching effect[35].

Although classical ideas are relevant to the description of the vibrational frequencies, they have not yet been helpful in discussions of damping. The classical concept for dissipation in extended systems is viscosity, and attempts have been made to apply this idea to the nuclear vibrations. Unfortunately, there is no fundamental justification for viscosity; it is only valid when particles have short mean free paths. In nuclei, the particles can travel completely across the nucleus with a high probability. The nuclear surface probably plays a more important part in the damping than do collisions between particles in the interior. A simple description of the damping in these circumstances is needed not only for the understanding of nuclear vibrations, but also for interpretation of data on heavy ion collisions.

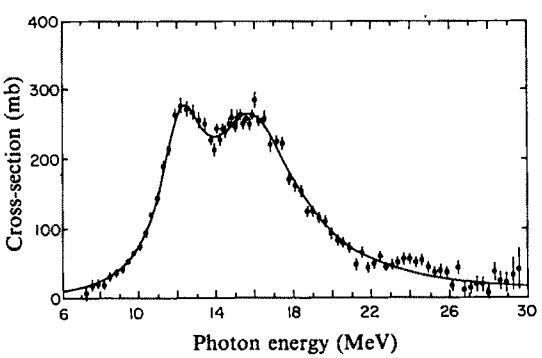

Fig. 11 The giant dipole resonance is ^{150}Gd, an ellipsoidal nucleus (ref. 3, Fig. 28). The curve is a sum of two lorentzian functions, the upper having twice the area of the lower.

Prospects

What is the likelihood of discovering more vibrations? The possibility of more complex motion always exists, and other vibrations can be calculated in RPA. However, all the other modes of particle displacement have a higher mean frequency. The damping is predicted to be much larger, both within RPA and due to the coupling to other degrees of freedom. Thus it is unlikely that a coherent mode, containing most of the sum rule, will be resolved as a distinct peak. In the inelastic scattering experiments, the spectrum contains a smooth background together with the presently known peaks, as may be seen in Figs 3 and 4. Part of this background at least must be due to highly damped vibrations of greater complexity. Without some specific measurable characteristic, however, it is not possible to identify them as such.

A 30,000-yr isotope climatic record from Antarctic ice

C. Lorius*, L. Merlivat†, J. Jouzel† & M. Pourchet*

* Laboratoire de Glaciologie du CNRS, 2, rue Très Cloïtres 38031 Grenoble Cedex, France
† Laboratoire de Géoisotopie de l'Eau, DRA Saclay, B.P. 2, 91190 Gif/Yvette, France

Simple glaciological conditions at Dome C in east Antarctica have made possible a more detailed and accurate interpretation of an ice core to 950 m depth spanning some 32,000 yr than that obtained from earlier ice cores. Dated events in comparable marine core has enabled the reduction of accumulation rate during the last ice age to be estimated. Climatic events recorded in the ice core indicate that the warmest Holocene period in the Southern Hemisphere occurred at an earlier date than in the Northern Hemisphere.

ALTHOUGH the stable isotopic composition ($^{18}O/^{16}O$, D/H) of polar ice sheets can provide a continuous record of past climatic conditions, the interpretation of the isotope profiles in terms of climatic temperature changes over a time scale ranging back to the last ice age is complicated by several factors including: (1) the determination of the time scale; (2) the influence of the elevation at which the snow was deposited and of ice sheet stability; (3) the establishment of a transfer function from isotopic δ ratio to temperature in past conditions. Despite these limitations the study of ice cores has already provided very useful palaeoclimatic data[1-5]. Similar limitations occur in the interpretation of other indirect sources of climatic data.

As isotopic records from areas near an ice divide are simpler to interpret, thermal core drilling to 906 m depth was carried out at Dome C (74° 39′ S; 124° 10′ E; elevation: 3,240 m, mean annual temperature: −53.5 °C, Fig. 1) during the 1977–78 Antarctic field season as part of the International Antarctic Glaciological project[6].

The isotope profile

The core recovery was about 98%. Sampling was carried out in the field by cutting a continuous slice from along the length of cleaned ice core. The $^{18}O/^{16}O$ ratios were measured with a fully automatic double mass spectrometer with an accuracy of 0.15‰ in the δ scale relative to the V. SMOW. The results averaged for samples of about 4 m length are plotted in Fig. 2 with depths expressed in metres of ice equivalent to take account of the

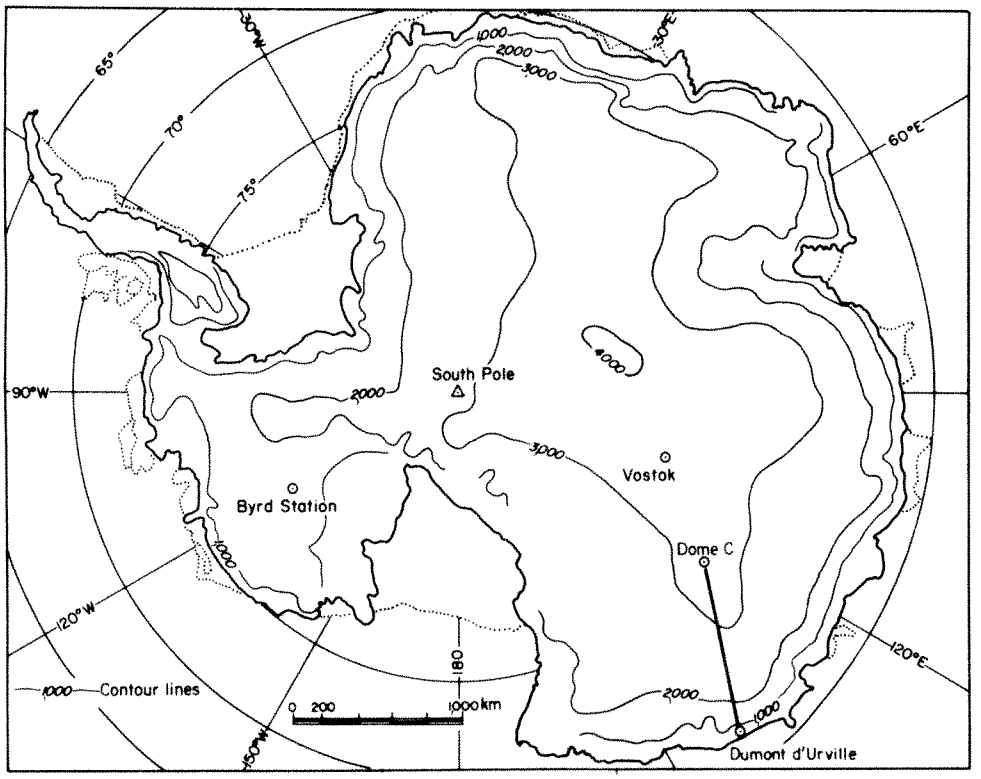

Fig. 1 Map of Antarctica showing the location of several stations (including the drilling sites) and of the traverse from Dumont d'Urville towards Dome C (dashed line). Recent data[32] indicate a dome-like shape around the Dome C site.

lower densities in the upper firn layers. Each increment samples a time interval a little longer than one century. A smooth curve was drawn from adjustment on the basis of a spline function of the order of 2 with a parameter of adjustment $\rho = 0.001$. The main features of the δ curve indicate relatively uniform conditions down to 381 m, with a mean value of −49.9‰ (standard deviation $\sigma = 0.46$) followed by a rapid decrease down to 510 m. From then and down to 687 m δ fluctuates around −55.3% ($\sigma = 0.37$); isotopic fluctuations and presumably those of climate are of similar magnitude in this depth interval to those of the upper 381 m, when mean values over the order of 100 yr are considered. The general trend is then towards less negative values down to the bottom (875 m, ice equivalent). Significant events are superimposed on these main features; some of these are indicated in Fig. 2.

Ice core chronology

Different methods may be used for dating deep ice cores[7,8] including measurements of radioactive decay, periodic changes of various parameters, and specific horizons dated from other sources. Some of these studies will be performed later, although they may not be successful in the low accumulation of the Dome C area. At present, a preliminary time scale can be calculated from the simplest ice flow model[9] which assumes a uniform vertical strain rate and a constant value of snow accumulation. Although this model has other limitations[10] it can be applied with reasonable confidence to ice dome areas when bedrock is flat and when considering the upper part of the ice sheet; both these conditions are fulfilled for the Dome C ice core. However, a large uncertainty results from the assumption of steady-state conditions over a time range which goes back to the last ice age. This is particularly true for the rate of snow accumulation which has so far been determined only over the past 25 yr from the radioactive layers formed from nuclear tests (0.037 m ice $yr^{-1} \pm 0.004$). The age of the ice (t yr) with depth can be calculated from

$$t = \frac{H}{\lambda} \ln \frac{H}{H - z} \qquad (1)$$

where λ is the accumulation rate, H the total ice thickness (3,400 m) and z the depth, all expressed in metres of ice equivalent. The ages so calculated are given in Fig. 2 (numbers in parentheses).

If the main isotopic features reflect climatic changes, we can try to get chronological information from climatic records obtained from other sources. Data from continental areas of the Southern Hemisphere are scarce but some reference data may be obtained from marine sediment cores which provide a climatic record of surface seawater temperature, assuming that typical climatic events are synchronous with those recorded in Antarctic snows. Previous results[11] from core MD 73025 (Indian Ocean; 43° 49′ S, 51° 19′ E) have been provided by J. C. Duplessy and G. Delibrias (personal communication). Eight ^{14}C ages were determined on the top 3.5 m of this core and the comparison of pelagic and benthic foraminifera isotopic profiles shows that some of the characteristic events recorded in the Dome C ice core are also apparent in this marine core. The selected climatic features can be seen in Fig. 2; depth in both cores with the three ^{14}C interpolated marine sediments ages are given in Table 1. According to Duplessy these climatic features can be recognised in several northern and southern ocean deep-sea cores having a high accumulation rate with roughly the same ^{14}C ages within experimental errors.

Table 1 Depth and interpolated marine sediment age of Dome C and MO 73025 cores

Dome C ice core Depth (m ice equivalent)	MD 73025 marine core Depth (m)	MD 73025 marine core ^{14}C (yr)
381	2.36 ± 0.02	10,550 ± 300
437	2.82 ± 0.02	12,600 ± 300
510	3.10 ± 0.05	15,500 ± 500

Snow accumulation rate changes

From these marine dates, we calculate by equation (1) a mean rate of snow accumulation in different ^{14}C time intervals. This gives 0.038 m yr^{-1} for the past 10,550 yr, 0.031 m yr^{-1} from 10,550 to 12,600 yr BP and 0.029 m yr^{-1} from 12,600 to 15,500 yr BP.

Although there are many uncertainties in such an approach and the accuracy of the accumulation figures may not be better than 10–15% (Table 1), the two last values are based on differences between ^{14}C ages, thus reducing problems of a possible time lag between marine and ice records and of errors of ^{14}C dating.

The rate of accumulation over the past 10,000 yr agrees very well with the value (0.037) measured over the past 25 yr. Since we know there are short-term changes in the accumulation rate this may seem to be a coincidence. However, the conclusion that present-day accumulation rates are typical of those for the past few thousand years has already been stated[12] for both the Greenland and Antarctic ice sheets from dating[7] and inferred from observed temperature–depth gradients[13]. Our figures suggest a decrease of the rate of snow accumulation associated with colder climatic conditions, the accumulation 14,000 yr ago being about 75% of the present value.

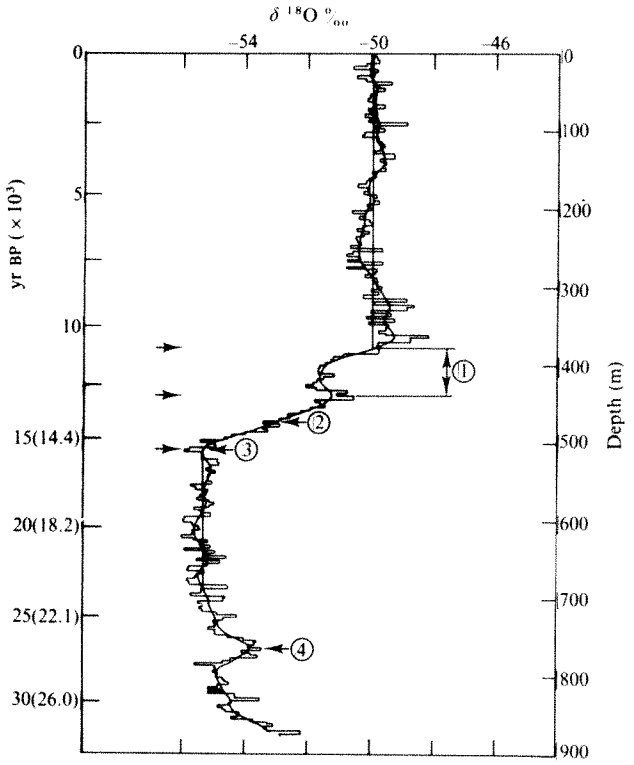

Fig. 2 δ record from the Dome C ice core plotted for about 4-m long increments and smoothed curve. The straight lines indicate mean values over the past 11,000 yr and during the late part of the last ice age. Significant isotopic events are numbered on the right hand side. On the left hand side arrows indicate reference levels corresponding to ^{14}C dates obtained from marine sediments. All depths are expressed in metres of ice equivalent. Ages are estimated from a simple ice flow model assuming a variable or constant (numbers in brackets) rate of accumulation.

Note that the mean annual accumulation in Antarctica is primarily governed by the amount of water vapour that can be carried in the atmosphere circulating above the surface inversion layer[12]. This is governed by the atmospheric temperature and by the saturation water vapour pressure over ice above the inversion. For condensation temperatures of around −40 °C in the Dome C area, a ratio of 0.75 for the vapour pressures corresponds to a condensation temperature change of about 3 °C.

The study of precipitation[14] at the South Pole gives a gradient of $d\delta^{18}O/dT_c = 1.4‰$ per °C, where T_c is the condensation temperature obtained from radiosonde measurements of cloud temperature. Analysis of snow samples collected between Dumont d'Urville and Dome C (Fig. 1) has provided an empirical relationship[15] between the mean surface temperature T_m and the isotopic deuterium content of $\delta D‰ = 6.04\ T_m$ (°C) −51 equivalent to $d\delta^{18}O/dT_m = 0.75‰$ per °C. In Antarctica mean temperatures above the atmospheric inversion layer (T_i) are similar to the condensation temperatures[12], while the inversion strength is linearly related[16] to mean surface temperature. A survey of existing data for eight stations with T_m values in the range from −10 to −56 °C gives $dT_i/dT_m = 0.67$ with a correlation coefficient of 0.99. Assuming $T_i = T_c$ leads us to interpret our traverse results of equivalent to $d\delta^{18}O/dT_c = 1.1‰$ per °C, a value which is in reasonable agreement with that obtained at the South Pole.

A change of 3 °C for the temperature of condensation previously deduced from accumulation data would lead to a change of 3.3‰ between ice recently deposited and that deposited 14,000 yr ago. The agreement with the value obtained from the Dome C record (3.1‰) is very satisfactory considering the large number of assumptions involved, which confirms conclusions about snow accumulation changes inferred from the Indian Ocean marine core data.

To obtain a continuous time scale we use relation (1) with a constant rate of accumulation (0.037 m ice yr^{-1}) down to a depth of 381 m, and then decreasing to 75% of this value down to 510 m; this last figure is used down to 687 m. Further down it does not make a significant difference whether or not we assume an increasing accumulation linked to the $\delta^{18}O‰$ change. The calculated time scale is given in Fig. 2. According to this model the age of the bottom of the 905 m deep ice core is about 32,000 yr.

Climatic interpretation

Two other ice cores with depths comparable or greater than that from Dome C have been recovered in Antarctica (Fig. 1). At Byrd Station (80° 01′ S, 119° 31′ W) the 2,160-m deep ice core covers a much longer time period and the isotopic change towards much more negative values is located between 1,000 and 1,400 m. The location and characteristics of the Vostok ice core are more comparable to those of Dome C one, the isotopic change at Vostok occurring between 250 and 375 m. Part of the published[2,17] isotope profiles plotted against ages are shown in Fig. 3.

Comparison of Figs 2 and 3 shows similar trends in the three δ profiles. Event 1 from Fig. 2 is well marked in all three locations and there is a parallelism between the Byrd and Dome C isotopic profiles down to event 3. Events 1, 2 and 3 are also apparent in the Vostok ice core when looking at a more detailed isotope profile[4], although there is a large scattering of the δ values probably due to discontinuous sampling technique. The less negative values of event 4 are also observed in the other ice cores.

Dating problems make precise age comparisons difficult, but it must be pointed out that the depths of the four events in the Vostok and Byrd ice cores relative to that of the Dome C record show a rather constant value. For the Vostok ice core where $\lambda = 0.024$ m ice yr^{-1} this value is similar to the ratio of the present rates of snow accumulation; this is not the case for the Byrd ice core, probably due to the very complicated regime in this area.

It appears then that the main characteristics of the δ profiles are similar for east Antarctica (Dome C, Vostok) and west Antarctica. Thus they probably reflect climatic events which affected both east and west Antarctica, rather than any ice sheet instability[18] because these two distinct areas have very different glaciological regimes. Furthermore, isotopic events observed in the Dome C ice core are also seen in the record of sea-surface temperature changes in marine sediments.

The ice core chronology from Dome C indicates a relatively cold period from 11,000 to 13,000 yr BP; this is shown also in the record of past temperature of the New Guinea Highland sum-

marised in ref. 19 from careful pollen analysis. The Dome C fluctuations observed during this period could be equivalent to the European Dryas–Bölling–Alleröid stages depicted in the Camp Century (Greenland) ice core[1] although dating uncertainties prevent any conclusion about their synchronism.

The last major glacial peak occurs around 16,000 yr BP, which agrees with the much less detailed pollen record from New Guinea[19] and the indication from various sources[20–22] that continental warming had probably begun in the Australian–New Guinea area by 16,000 ± 2,000 BP. This worldwide climatic feature has been found in many marine sediment cores both in the Northern and Southern Hemispheres[23,24] with an age of about 18,000 yr which may vary locally by several thousand years.

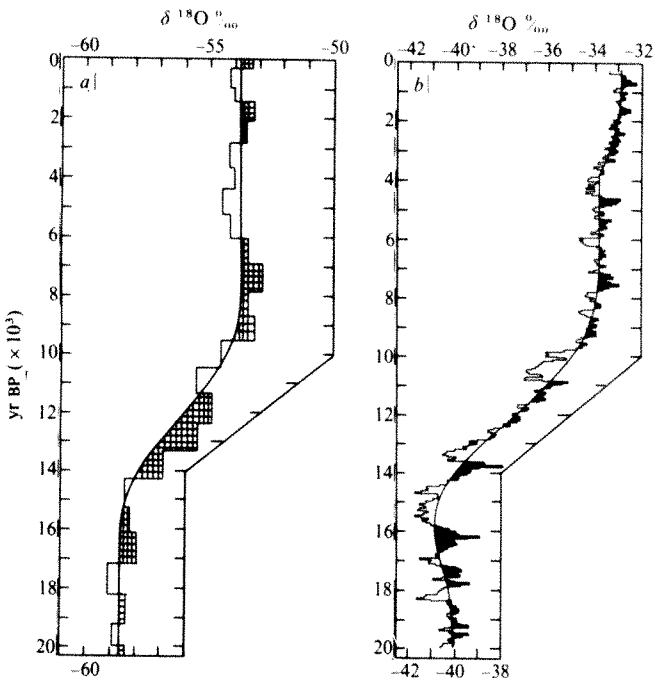

Fig. 3 The Vostok (*a*) and Byrd (*b*) δ records during the past 20,000 yr from ref. 2 (Byrd) and ref. 17 (Vostok). The δ values exceeding the smoothed curves are shown in black.

The warmer conditions shown on the Dome C δ record before 25,000 yr BP also agrees with conditions observed around this time in New Guinea by pollen analysis[22] and with North America glacial chronology[25].

The isotopic shift associated with the transition from the coldest part of the ice age towards mean climatic conditions from the last 10,000 yr is 5‰ for Vostok[4], 7‰ for Byrd[2] and 5.4‰ for Dome C. When values for Vostok and Byrd station are corrected[12] to allow for the origin further inland of the deeper ice and for a higher surface elevation of the ice sheet during the last ice age, the δ^{18}O‰ change associated with climatic changes would become 4.5 (Vostok) and 5.3 (Byrd). Although corrections for the same factors at Dome C could be made if measurements of total gas content[26] were available, severe cracking in the ice core from Dome C has made such a study impracticable. Since Dome C is at present a centre of outflow and if we assume that the form of the ice sheet has changed little over the past 10,000 yr, then the δ values in the upper 381 m of ice core should provide a useful climatic record over this period.

However, at the end of the last ice age, a lower sea level may have resulted in a slightly expanded ice sheet over east Antarctica, leading to greater ice thicknesses and increased surface elevations. These effects would be much greater in coastal areas, while in central east Antarctica estimates of the consequent surface rise are around 100 m (refs 4, 28). Such a rise, together with the present δ-elevation gradient observed in the Dome C area[15] would involve a correction of 1.5‰ to allow for changed elevation during the ice age. Thus it seems that the climatic change at the end of the last ice age was similar at Dome C, Vostok and Byrd, but further studies of ice thickness changes at Dome C are needed to confirm this conclusion.

The isotopic shift has still to be corrected for modifications of oceanic parameters during the last ice age. The most obvious is the change of mean isotopic value of oceanic waters. Due to the storage of water in δ-depleted ice sheets an increase of 1.6 δ^{18}O‰ with reference to the present conditions has been estimated[11]. This effect will probably be reflected in antarctic precipitation but from previous discussion it could be compensated by greater ice thickness during the last ice age.

The isotopic composition of ice cores, although principally governed by the temperature of condensation, can be affected by many other parameters[1]. However, it has been suggested[12] that the present empirical relationship between mean surface temperature and isotopic content may not have been too different in Antarctica during the last ice age. As previously mentioned a 0.75‰ per °C δ^{18}O change was obtained in this area for a large range of temperatures, which leads to a tentative estimation of a difference of about 7 °C for the surface temperature between the coldest part of the ice age and the present climate. From previous discussions the suggested changes for the temperatures of condensation and above the inversion layer are reduced by about half.

Although there are many assumptions in such interpretations, they agree with the results of atmospheric modelling of the ice age (18,000 yr BP) climate[29,30] which also indicate lower precipitation during cold conditions comparable with those described here. For the past 11,000 yr the climatic record inferred from the δ profiles (Fig. 2) shows that the warmest conditions occurred during the period 11,000–8,000 yr BP and the coldest conditions from about 8,000 to 4,000 yr ago. For the past 4,000 yr we observe a moderately warm period followed by a slight trend towards less positive δ values, with present surface conditions close to the mean value for Holocene.

Figure 3 shows that the Vostok δ profile indicates the same succession of climatic periods with a slightly different chronology. However, the Byrd record shows no apparent agreement with this sequence[2] due to the difficulty of interpreting its complicated glaciological regime.

The lack of comparative data from the Southern Hemisphere makes it difficult to estimate the spatial representativity of the Dome C Holocene record. During this period, the climatic evolution inferred from our δ profile gives a different picture from that obtained from New Guinea pollen analysis[19,20]. The warmest period (11,000–8,000 yr BP) that we observed at the end of the transition from the last ice age is much earlier than the usual estimates for the so-called hypsithermal in the Northern Hemisphere. This is, however, in excellent agreement with the fact that the warmest sea surface temperature since the last glacial age[31] in the Southern Hemisphere have a radiocarbon date of 9,400 yr (24).

Shelf sea fronts' adjustments revealed by satellite IR imagery

J. H. Simpson & D. Bowers

Marine Sciences Laboratories, University College of North Wales, Menai Bridge, Anglesey, UK

IR imagery from NOAA 5 has been used to study the movement of shelf sea fronts. After the elimination of tidal advection, the fronts show remarkable consistency of position and do not adjust to the strong semi-monthly variation in tidal stirring which indicates the operation of a feedback process in vertical mixing.

IR IMAGERY from NOAA 4/5 has provided convincing evidence of the role of tidal mixing in controlling the distribution of sea surface temperatures in the European shelf seas. In particular it has been shown that the positions of the surface manifestations of the shelf sea fronts are closely parallel to contours of the h/u^3 parameter[1,2], as previously predicted[3].

As the archive of imagery grows, it should be possible to use it to answer more detailed questions about the evolution of the fronts and the processes occurring on them. Indications have already been obtained from several images of the development of large scale (~25 km) instabilities in the along front flow which are clearly important as agencies of cross-frontal mixing[1,4].

In this article we attempt a more systematic analysis of two years data from NOAA 5 to investigate the extent to which the mean positions of the fronts adjust to variations in both the rate of tidal mixing and the surface heat flux.

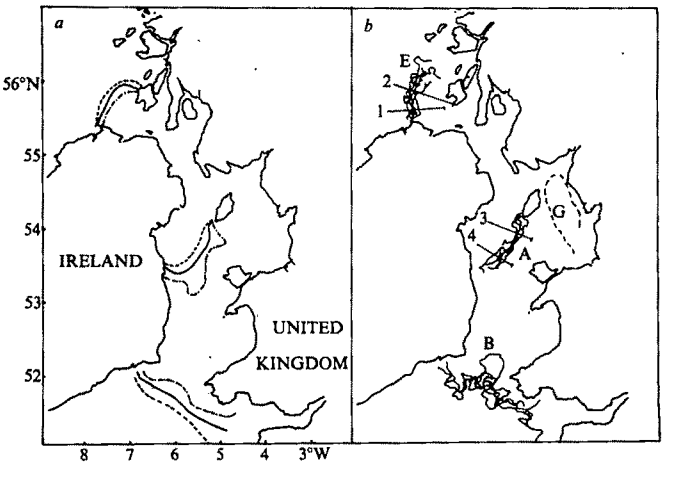

Fig. 1 *a*, Contours of $\log_{10} h/u_s^3$ -·-· 1.5; —— 1.9; – – – 2.2. h Is the depth (m) and u_s is the tidal stream amplitude at springs (m s^{-1}). The separation of the contours 1.5 and 2.2 indicates the range of hypothetical adjustment between neaps and springs. Contour shape based on Pingree and Griffiths[2]. *b*, Composite of all frontal positions observed in July 1977 from NOAA 5 imagery. Fronts are labelled as follows: A, Western Irish Sea (WIS); B, Celtic Sea; E, Islay; G, Liverpool Bay. Reference lines, along which displacements were measured, are numbered.

Equilibrium adjustment

We particularly wish to examine the possibility that the mean frontal positions vary during the semi-monthly range cycle of the tides. As the amplitude of the tidal streams increases by a factor ~1.8 from neaps to springs, the intensity of tidal dissipation, which is proportional to u^3, will rise by a factor ~5.8. The balance between surface heating and tidal and wind stirring at a front may be expressed in a constant efficiency model[1] as

$$R = 1 - a\left(\frac{\overline{u^3}}{Qh}\right) - b\left(\frac{\overline{w^3}}{Qh}\right) = 0$$

where h is the depth; u the tidal stream velocity; w the windspeed; Q the surface heating rate, and the parameters a and b, which contain the efficiencies of tide and wind mixing, may be assumed constant. The overbar denotes a time average.

If we further assume that Q and $\overline{w^3}$ are spatially uniform over a particular frontal region, the 'equilibrium positions' should be defined by

$$\chi = \frac{h}{\overline{u^3}} = \text{constant}$$

and, for slow changes in $\overline{u^3}$, the front would move to the appropriate contour of χ. This hypothetical adjustment, for a range change corresponding to the phase inequality cycle is shown in Fig. 1*a*. In the case of the Islay front, for example, the equilibrium displacement would be ~20 km. In other frontal

© Macmillan Journals Ltd 1979

Fig. 2 NOAA 5 IR image from 21 May 1978, at 09.30 GMT, showing Islay and WIS fronts.

regions this movement would be generally larger due to the weaker gradients in χ.

On the other hand, if the time scale for adjustment is long in relation to the fortnightly mixing cycle, adjustment may be substantially reduced. The mixing model of James[5], which incorporates a vertical transfer rate dependent on Richardson number, and hence stability, predicts negligible movement. Over longer periods we might also anticipate that the mean position of the front would adjust to changes in the heating rate Q which, at latitude 55° N, falls from a maximum of $\sim 140\ \mathrm{J\ m^{-2}\ s^{-1}}$ in mid-summer (day 172) to $\sim 30\ \mathrm{J\ m^{-2}\ s^{-1}}$ at 31 August (day 243) and reaches zero around mid September. Less regular adjustments due to variations in the level of wind mixing are also a possible source of variability in frontal positions.

Data acquisition and processing

The analogue data from the 10.5–12.5 μm band radiometer on NOAA 5 are received at the University of Dundee where they are converted to imagery with appropriate grey scales by a modified photo-facsimile machine. In the example shown in Fig. 2, where the darkness of the image increases in proportion to the radiation temperature, the positions of the Islay and western Irish Sea fronts are clearly visible. The 'front' is here taken to be the point of maximum surface gradient in sea surface temperature as judged from grey scale changes on the analogue images. Direct observations at sea indicate that it is close to, though not exactly coincident with, the transition to complete vertical mixing.

The photographs are corrected, by analogue techniques, for geometric distortion due to slant angle viewing of the Earth's surface from the spacecraft. As we are using the imagery to detect relatively small displacements of geographical position, it is important to quantify the extent of any residual distortion in the imagery. We have estimated this by determining, from a series of images, the relative positions of two headlands whose separation is known. The standard deviations of 17 measurements was $\sigma = 1.4$ km for a separation of 61 km, a value which is representative of the distance from coastal reference points at which fronts are located. With increasing distance from the coast the relative uncertainty of positions will be larger, while close to land it is limited by the spatial resolution of the scanner which is ~1 km.

For each cloud-free picture of a frontal region the displacement of the front along lines approximately perpendicular to the mean frontal direction was measured from a datum marker. Figure 1*b* shows the location of the reference lines together with a superposition of tracings of the frontal positions as seen on all the useful images during July 1977. The number of cloud-free views shown here is typical of the data yield for summer months. Other fronts, notably one evident in the original pictures in Liverpool Bay (Fig. 2) will be described elsewhere.

An indication of the variability of frontal positions may, of course, be obtained from composite diagrams like Fig. 1*b* but note that the apparent displacement here includes a contribution from tidal advection, by the stream component normal to the front, which may be as great as ±8 km. To remove this, we considered the attractive possibility of using the known times of sampling, which defines the relevant phase of the tide, together with the observed positions of the fronts to extract the tidal streams by regression analysis. This approach is feasible and an example is given below but there is an inherent danger. As the satellite is Sun-synchronous the sample time is constrained to essentially the same time each day. For the UK the morning pass occurs on average at ~10.00 GMT. Consequently the principal solar constituent S_2 in the tidal signal is sampled at an almost constant phase while M_2 is observed with a phase slowly changing at a rate of $24.38°\ \mathrm{d^{-1}}$. This generates an apparent displacement with a semi-monthly periodicity as can be seen in Fig.

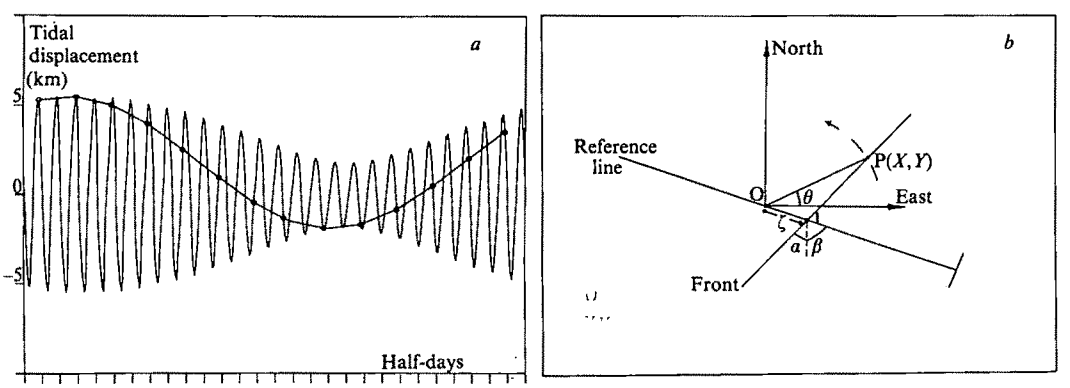

Fig. 3 *a*, Predicted tidal displacements for Islay line 2 based on current meter determination of M_2 and S_2. Circles indicate the effect of sampling daily at a fixed solar time of 10.00 GMT. The result is a signal of semi-monthly periodicity which may be ambiguous with springs–neaps adjustment. *b*, Displacement of the intersection point I of the front and reference line by an elliptical tidal excursion of a water particle P about its mean position 0.

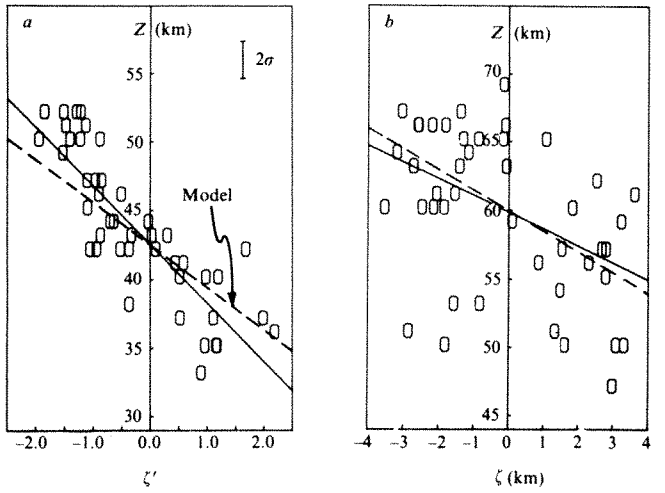

Fig. 4 Displacement Z versus a, predicted tidal displacement ζ' for Islay line 1, and b, predicted tidal displacement ζ for Islay line 2. The continuous lines are the results of a least squares fit. The dashed lines are based on a numerical model.

3a. This displacement will be indistinguishable from the neaps–springs mixing adjustment if the phases coincide. For a two component tide it can be shown that the phase difference of the range cycle and the apparent displacement is just

$$\Delta\nu = \phi_s - \omega_m \tau$$

where ϕ_s is the phase lead of the solar tide, ω_m is the frequency of the lunar tide and τ is the time before midday at which sampling takes place.

Ideally the ambiguity should be removed by doubling the sampling frequency using data from two satellites. In practice this is hardly necessary because of the spread in sampling time (±1.5 h) about the mean and the fact that the evening pass occurs on average 10 h (not 12 h) after the morning transit, an asymmetry which results from the inclination of the satellite orbit to the Earth's axis.

If an adequate sample of velocity data is available from a mooring near the front, prediction of tidal displacements X and Y of a water particle may be made by the usual harmonic method according to

$$X = \sum_1^N \frac{a_i}{\omega_i} \sin(\omega_i t + \kappa_i) \quad \text{and} \quad Y = \sum_1^N \frac{b_i}{\omega_i} \sin(\omega_i t + \lambda_i)$$

where the a_i, b_i, κ_i, λ_i are the amplitudes and phases determined by least squares harmonic analysis of the velocity data. The displacement of the front along the reference line, which is not the same as the displacement of a water particle, may then be found from

$$\zeta = \frac{(X^2+Y^2)^{1/2}\cos(\theta+\alpha)}{\sin(\alpha+\beta)} \quad \text{where} \quad \theta = \tan^{-1} Y/X$$

where the angles are defined in Fig. 3b. This approach assumes that the front is straight for a length large compared with the section of it which crosses the reference line during a tidal cycle. This requirement is least severe if we choose β so that $\alpha+\beta = \pi/2$, when the range of ζ has a minimum.

Where adequate tidal stream data is not available, we have compared the observed displacements to a non-dimensional tidal displacement defined by

$$\zeta' = F(t)\sin(\omega t + \phi)$$

where ω is the semi-diurnal tidal frequency and ϕ is a phase lead determined by reference to tidal atlas data. The slowly varying factor $F(t)$ is defined by

$$F(t) = \frac{\text{Elevation range at time } t}{\text{Elevation range at mean neaps}}$$

and found from elevation predictions at a convenient port. Comparison of ζ and ζ' in a case where suitable data were available showed acceptable agreement with an r.m.s. difference of 1.1 km.

Results

The Islay front: The tidal advection signal is illustrated in Fig. 4 where the observed displacements Z on lines 1 and 2 have been plotted against ζ' (Fig. 4a) and ζ (Fig. 4b). In the latter case, current meter data were available from a closely adjacent current meter station[6]. The slope of the regression line is 1.22 with a standard deviation of slope $\sigma_m = 0.44$, so that the observed displacements are consistent with the predictions although the scatter is considerable.

A better fit is apparent in Fig. 4a in which a regression line is compared with an estimate based on the numerical model of Pingree and Griffiths[2]. The difference in slope (1.1 km) is significant at the 1% level, but this may partly be due to the interpolation of values between model grid points in a region of high gradients. The observed slope difference corresponds to a change in position of only one grid interval of 9 km.

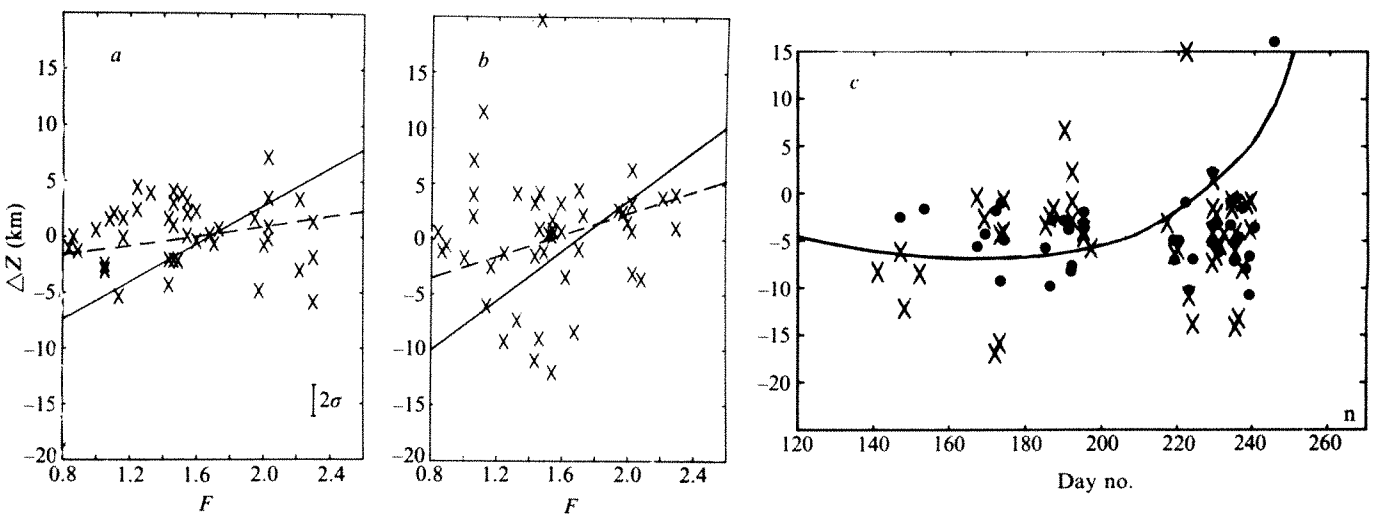

Fig. 5 a And b, residual displacement ΔZ against non-dimensional range index F for a Islay line 1; b Islay line 2. The extent of equilibrium adjustment is shown by the solid line. The dashed line has the largest slope consistent with the data points at 95% confidence ($F = 1$ at mean neaps). c, Residual displacement ΔZ versus day number n for the Islay front: ●, line 1; ×, line 2. The curve shows the form of the equilibrium adjustment to the seasonally variable heat flux.

An alternative explanation is the distortion of the Z–ζ relationship by curvature of the front, which we have neglected. When sufficient data are available, systematic departures from a straight line may be used to estimate frontal curvature and distinguish between fixed meanders and evolving eddies whose contributions should be random.

Subtracting the tidal advection signal, we obtain estimates of the residual displacement ΔZ which are plotted against tidal range in Fig. 5 along with a line which represents the extent of equilibrium adjustment. The data points are clearly inconsistent with such adjustment and the slope of the regression line through them is not significantly different from zero. The most probable adjustment between neaps ($F = 1$) and springs ($F = 2$), is determined from the regression as 0.25 km for line 1 and 1.2 km for line 2. Upper bounds are 1.9 and 4.8 km respectively at the 95% confidence level.

The marked difference in scatter between the two lines is apparently due to the front's tendency to form eddies which increases northwards. The lack of such instabilities on the Islay front near the Irish coast contrasts with that commonly observed on the shelf sea fronts, and may mean that observations of adjustment here are untypical of these features. Moreover the Islay front exhibits a strong salinity contract which distinguishes

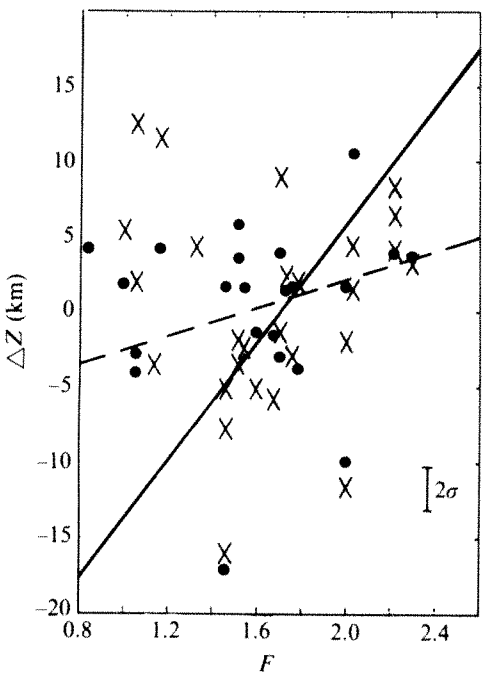

Fig. 6 Residual displacement ΔZ versus non-dimensional tidal range F for western Irish Sea lines 3 and 4 combined. (●, line 3; ×, line 4.) The extent of equilibrium adjustment is shown by the continuous line. The dashed line has the largest slope consistent with the data points at 95% confidence ($F = 1$ at mean neaps).

it from most other fronts and may contribute to anomalous behaviour. We therefore consider a second example.

The western Irish Sea: In this case density is essentially controlled by temperature. A second difference is that the tidal streams are almost parallel to the front so that the tidal advection signal is weak. After subtracting an estimate of ζ based on numerical model results[2], we have obtained the estimates of ΔZ for both lines 3 and 4 which are plotted against tidal range F in Fig. 6. As in the case of the Islay front, there is no evidence of semi-monthly adjustment. The most probable neaps to springs adjustment is 0.7 km with an upper bound, at 95% confidence, of 4.5 km.

The relatively large scatter is again probably due to frontal meanders and eddies (see Fig. 1*b*) which frequently occur on this front.

Seasonal and other adjustments

To test for frontal movement on a longer time scale, we have plotted ΔZ versus Julian day number n in Fig. 5*c*, together with an estimate of adjustment based on the mean nett heat flux through the sea surface. The scatter of points is such that a seasonal trend cannot be reliably identified with the present data, particularly as there are very few data points after $n = 240$ when the seasonal effect may become conspicuous. Moreover, because of the stored potential energy deficit, the retreat of the front may be slower than predicted by an equilibrium model especially as $Q \to 0$ at the autumnal equinox. Note also that the sampling scheme is biased, in the sense that images are most often available during anticyclonic weather conditions when surface heating will be above average. This may account for the large cluster of points with low values of ΔZ occurring between days 220 and 240. A large proportion of these points are from images during a period of exceptional fine weather in August 1976.

If the observed displacements from the mean position are not semi-monthly or seasonal in origin, to what, apart from frontal instabilities, could they be attributed? One possibility is that they represent movement induced by large scale advection. The residual velocity field in the Irish Sea, averaged, over periods of ~1 month, is small and not known with confidence, but over shorter time scales, residual flows of a few centimetres per second probably occur[7] and these could be responsible for fluctuations in the frontal position of the observed magnitude of $\simeq \pm 5$ km.

To assess the relevance of this hypothesis, we have examined the data for coherent adjustment on adjacent reference lines. No significant correlation is found for example, between ΔZ on lines 1 and 2 for the Islay front, implying that other movements with a length scale shorter than the line spacing of 30 km, are dominant.

Discussion

The results reported here indicate that any adjustment of the shelf sea fronts to the semi-monthly mixing cycle is minimal. There is also little support in the data for the notion of seasonal positional adjustment between June and the end of August. The shelf sea fronts therefore represent a set of almost fixed geographical boundaries throughout the summer season, moved significantly only by tidal advection.

There remains the possibility of regular adjustment on a very small spatial scale ~2 km, which cannot be resolved by the present approach, but which may be of considerable biological importance. It may be significant that the three regression coefficients of ΔZ versus F, although small, are all positive, which is the sense of the anticipated adjustment.

The remarkable consistency of frontal positions confirms the prediction of the James model and points to the operation of a feedback process in determining the rate of vertical mixing, that is, once stratification is established the efficiency of mixing falls, so that even when stirring increases at spring tides, the stratified structure survives. The notion of feedback is also consistent with the results of mixing tank experiments[8] which indicate that the flux Richardson number (efficiency) decreases with stability above a threshold stability level. An interesting experiment described by Loder (unpublished) suggests that direct laboratory study of this hysteresis effect may be profitable.

The nitrogen budget of a salt marsh ecosystem

Ivan Valiela & John M. Teal

Boston University Marine Program, Marine Biological Laboratory, Woods Hole, Massachusetts, and Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

Salt marshes reduce oxidised nitrogenous compounds to ammonium and particulate nitrogen and export these reduced forms to coastal waters. The internal demands exceed the net inputs of nitrogen by rain, groundwater flow and fixation, suggesting very active uptake, conversion, release and recycling of nitrogen within a marsh ecosystem. Nitrogen losses are mainly through tidal exchanges and denitrification, and these two outputs balance the gains. The chemical exchanges among uplands, marshes and coastal water are important in structuring these ecosystems.

NITROGEN is a key nutrient in coastal ecosystems[1]. In salt marshes, nitrogen has a critical role in determining the function and structure of the ecosystem. Salt marsh floras receiving increased amounts of nitrogen show increased rates of primary production[2-5], the abundance of certain species changes and the nitrogen content of the plants increases[6]. Provision of excess nitrogen raises the per cent nitrogen in tissues of marsh grasses from levels typical of C_4 plants to those of C_3 plants[7,8]. This is important because low nitrogen content is one reason why C_4 plants are relatively free from herbivores[9]. The dominant plants (*Spartina alterniflora*, *S. patens* and *Distichlis spicata*) in salt marshes of the Atlantic coast of the US are C_4 grasses, but where the supply of nitrogen is increased the number of marsh herbivores increases due to the lowered C/N ratios in the plant tissues[6].

Increases in nitrogen supply also lead to increases in the activity and standing crops of decomposer organisms and detritus-feeding invertebrates as the percent nitrogen of the litter helps to regulate decomposers (unpublished results). In general, the biomass of invertebrates in salt marsh plots receiving added nitrogen is larger than in untreated plots. We have also found that increased nitrogen supply changes the morphology of stands of *Spartina alterniflora* from a short to a tall form[10]. Concomitant with this is increased spacing among the taller plants leading to a more open habitat which in turn allows predatory fish and crabs a greater chance of finding prey on the marsh surface[11]. Increases in the supply of nitrogen therefore enhance primary production, decomposer activity, secondary production and changes in the physical structure of a marsh environment that facilitate predation by fish. Thus the rate of turnover of the entire system to a large extent depends on nitrogen supply.

A second important feature of nitrogen in salt marshes involves the export of nitrogenous materials and marsh-produced organic matter to coastal waters. The proposition that marshes provide food for coastal and estuarine fin and shell fish populations, including economically important species, has been the main argument for conservation of coastal marshes. With the recognition that nitrogen has a limiting role for coastal phytoplankton production[1], it can be appreciated that nitrogen exchange between coastal waters and marshes is significant for both these ecosystems.

We present here the first complete nitrogen budget for a marine ecosystem where each of the various inputs and outputs from a salt marsh has been accounted for. Great Sippewissett Marsh, our study marsh, is located on the western shore of Cape Cod, Massachusetts. Seawater from Buzzards Bay flows into Great Sippewissett Marsh through a single entrance (Sippewissett Creek) and floods the marsh twice daily with a maximum tidal excursion of about 1.6 m. The total area of the marsh is 483,800 m^2 and includes muddy (104,900 m^2) and sandy (61,700 m^2) creek bottoms, algal mats (13,000 m^2), low marsh dominated by short (122,500 m^2) or tall (91,100 m^2) *Spartina alterniflora* and high marsh (89,300 m^2) where the grasses *S. patens* and *D. spicata* are found. The marsh is surrounded by glacial moraine on the south, east and north and by sand dunes to the west. The relief and the ground water table slope generally to the west and towards the marsh and bay.

Inputs and outputs

Nitrogen enters Great Sippewissett Marsh through precipitation and flow of groundwater, the latter flowing into the marsh through numerous small underground springs. Other sources of nitrogen are fixation of atmospheric nitrogen by blue-green algae and bacteria in the sediments. Tidal flushing brings in and removes dissolved and suspended nitrogen from the marsh. The second major loss of nitrogen is through denitrification. Other minor fluxes include volatilisation of ammonia, removal of shellfish, loss to sediments and deposition of faeces by roosting birds.

Groundwater flow. Groundwater was sampled over 2 yr at seven small underground springs that flowed from the upland into the marsh[12]. The amounts of ammonium, nitrite and organic nitrogen were determined using an autoanalyser. The total flow of groundwater into the marsh lowered the salinity of the ebbing tidal water by about 2‰. This lowered salinity was used to calculate the volume of freshwater contributed by groundwater. Salinities were collected routinely during entire tidal cycles through the year. With these estimates of concentrations and volumes, the amount of each nutrient entering the marsh at different times of the year was calculated (Fig. 1). Nitrate was the major inorganic nitrogenous constituent of groundwater (averaging over 50 $\mu mol\ l^{-1}$), with substantial amounts of dissolved organic nitrogen (DON) (Table 1). There was a small reduction of nitrate flow during the autumn (Fig. 1). The amount

Cover photograph shows false colour IR aerial view of Great Sippewissett Marsh, Massachusetts. The entire system is drained by Sippewissett Creek. The dark blue tidal creeks have muddy bottoms while sandy bottoms show as light blue. Small pannes with no obvious drainage are scattered through the marsh. Algal mats occur on sand flats (top right). The sand surface is very unstable except where consolidated by the grey–blue mats of blue-green algae and purple sulphur bacteria. The largest area of the marsh is low marsh, covered by *Spartina alterniflora* (dark pink). The taller stands of *S. alterniflora*, showing as a thin red ribbon, can be seen on creek banks. Above the elevation of the low marsh, visible as areas of lighter pink, is high marsh where *S. patens* and *Distichlis spicata* grow. The marsh is surrounded by upland vegetation on the glacial hills.

of ammonium increased in summer, presumably due to the increased decay of litter prompted by higher temperatures at that time of year. The amounts of nitrite involved were minimal and were not included in Fig. 1. The total annual input of nitrogen to Great Sippewissett Marsh by groundwater was 6,120 kg yr^{-1}.

Precipitation. The amount of precipitation and the concentration of ammonium, nitrate, nitrite, DON and particulate nitrogen were measured in rain gauge collections at various sites over 2 yr (ref. 12). Nutrient inputs for the four seasons was calculated by multiplying the concentrations of nitrogenous nutrients by the amount of rain for each rainfall. The nutrient concentrations were typical of semirural areas[13–15] and there was little seasonal change. Nitrate and DON were the principal forms of nitrogen delivered by rain (Fig. 2 and Table 1). The concentration of all nutrients was higher in the groundwater than in precipitation[12] primarily due to evapotranspiration by terrestrial vegetation. There is little evidence of any increase in nitrogenous concentration in groundwater due to leaching from septic tanks upstream. The volume of rain that fell on the marsh was much less than that which reached the marsh as groundwater, so only 380 kg yr^{-1} of nitrogen reached the marsh through rainfall (Table 1).

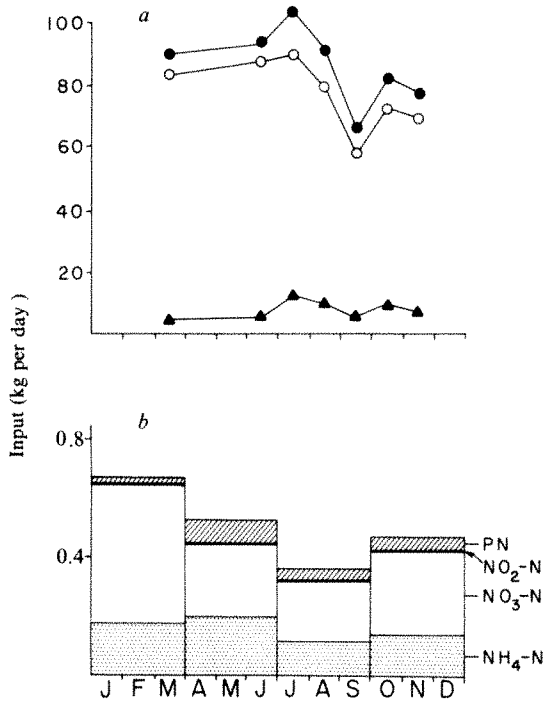

Fig. 1 Amounts of nitrogenous nutrients brought in by groundwater flow (*a*) and precipitation (*b*) into Great Sippewissett Marsh throughout the year. Values for precipitation are averaged for 3 months periods. Even though rain fell in episodic fashion, results are averaged on a per day basis over an entire 3-month period for ease of comparison with the other inputs and outputs. ●, Dissolved organic nitrogen; ○, NO_3—N; ▲, NH_4—N.

Nitrogen fixation by bacteria. Fixation of nitrogen by bacteria in the marsh is due to free-living bacteria in sediments lacking vegetation and bacteria closely associated with roots of marsh plants[16]. Rates of bacterial fixation in each of the marsh habitats were measured by incubating cores of sediment for 24 h in a gas mixture of 86% nitrogen, 10% acetylene, 4% oxygen. We then reflushed the headspace above the core with gas of a similar composition and measured ethylene production 24 h later by gas chromatography[17].

Low marsh was the major site of bacterial fixation due to the higher rates (100–500 ng N cm^{-2} h^{-1} during the warm part of the year) and larger area involved (Fig. 2). High marsh had lower rates (50–150 ng N cm^{-2} h^{-1}) and smaller area. Fixation peaked in the vegetated habitats during spring and early autumn, when roots were actively growing or senescence was taking place. Perhaps root exudates are most abundant at those times. Fixation rates in creek bottoms were considerably lower (maximum of 80 and 20 ng N cm^{-2} h^{-1} for muddy and sandy creeks) than in those recorded in sediments supporting plants and peak fixation occurred in midsummer (Fig. 2). Nitrogen fixation totalled 2,980 kg yr^{-1}.

Table 1 Nitrogen budget for Great Sippewissett Marsh (kg yr^{-1})

Processes	Input		Output	Net exchange
Precipitation		380		380
NO_3—N	110			
NO_2—N	0.4			
NH_4—N	70			
DON	190			
Particulate N	15			
Groundwater flow		6,120		6,120
NO_3—N	2,920			
NO_2—N	30			
NH_4—N	460			
DON	2,710			
N_2 fixation		3,280		3,280
Algal	297			
Rhizosphere bacteria	2,595			
Non-rhizosphere bacteria	384			
Tidal water exchange		26,200	31,600	−5,350
NO_3—N	390	1,210		
NO_2—N	150	170		
NH_4—N	2,620	3,540		
DON	16,300	18,500		
Particulate N	6,740	8,200		
Denitrification			4,120 (2,820)	−6,940
Sedimentation			1,295	−1,295
Volatilisation of NH_3			17	−17
Deposition of bird faeces		9		9
Shellfish harvest			9	−9
Totals		35,990	39,860	−3,870

Totals for each process are offset to the right. Losses from the marsh to Buzzards Bay are shown as negative numbers in the net exchange column. The amount of nitrogen added to the denitrification value is not equal to the amount of nitrogen fixed because net denitrification was not active in the blue green algal mats. Some of the values in this table and in the text may not agree with those of refs. 12, 16, 18, 20. The entries here were computed using corrected areas for the habitats and supersede earlier estimates.

Nitrogen fixation by algae. Algal fixation was measured for each habitat by an adaptation of the acetylene reduction technique[18]. Although pannes and algal mats had the highest fixation rates (up to 500–600 ng N cm^{-2} h^{-1}), the area of these habitats was so small that their contribution of N to the total marsh was small. Low marsh and creek bottoms showed lower rates[18] but their larger areas resulted in a greater contribution to the nitrogen economy of the marsh. The total nitrogen introduced into the marsh by algal fixation was 297 kg yr^{-1}, an order of magnitude smaller than that contributed by bacterial fixation.

Tidal exchange. The flow of seawater and nitrogenous nutrients through the mouth of Sippewissett Creek were measured during entire tidal cycles about monthly throughout the year. Water movement in and out of the marsh was measured with mechanical flow meters throughout each tidal cycle[12]. Tidal water was sampled hourly during each cycle and the concentrations of dissolved and particulate nutrients were determined. With these data and knowledge of the cross-sectional area and tidal height of Sippewissett Creek, water flux and nitrogenous nutrients entering and leaving the marsh during each hour of a tidal cycle were calculated. We summed over the tidal cycle to obtain net exchange (Fig. 3*a*).

Ammonium was the principal form of dissolved inorganic nitrogen (DIN), averaging about 1 μmol NH_4—N l^{-1} in winter and spring and 2–6 μmol NH_4—N l^{-1} in summer and autumn. For the first half of the year there were only trivial exchanges of

ammonium between the marsh and Buzzards Bay (Fig. 3*a*). From June to July there was a substantial import of ammonium into the marsh. This took place while the vegetation was actively growing and setting seed. The growth rate of *S. alterniflora* in Great Sippewissett Marsh is such that this species by itself consumes more than 39 kg per day of NH_4—N. During the same time of year about 9 kg per day of NO^-_3 and NH^+_4 nitrogen are brought into the marsh daily by groundwater (Fig. 3*b*). The tidal import of DIN into the marsh (Fig. 3*b*) was 8 kg per day, making a daily total of 17 kg DIN per day, a rate lower than the 39 kg per day used by plants during their period of active growth.

Towards the end of August there was a marked export of ammonium into Buzzards Bay (Fig. 3*a*), related to the maturity and senescence of marsh vegetation. The peak export of ammonium from the marsh was after the plants had matured and began flowering (Fig. 4); mature and senescent plants are most subject to leaching[19]. In a salt marsh with twice daily submergence in a good electrolyte, leaching should be important. Measurements of leaching of NH_4—N from marsh grasses show that such losses peak in August and that the standing crop of marsh grasses can release about 7 kg N per day through leaching (unpublished results).

In late summer the DIN conveyed into the marsh by groundwater (about 8 kg N per day), is no longer intercepted by the marsh ecosystem. Adding this amount of groundwater DIN to the 7 kg N per day leached from plants, a value (15 kg N per day) that is near the observed export of DIN (roughly 12 kg N per day) from the marsh to the Bay in late August and September is obtained (Fig. 3*b*). Perhaps additional ammonium is released by anaerobic respiration of plant exudates. In August the sediments become markedly more anoxic (B. Howes, personal communication). We are investigating the relationship between root activity and redox condition but as yet are unable to estimate the contribution of this mechanism to tidal export of DIN.

Nitrite is found in low concentration (up to 0.2 μg—at NO_2—N l^{-1}) in marsh water and it is difficult to know if the fluctuations seen in Fig. 3 (top) are of significance. Nitrate concentrations were higher (averaging up to 1 μmol l^{-1}), with net exports in autumn and winter (Fig. 3*a*).

Figure 3*b* shows the seasonal changes of total dissolved inorganic nitrogen. The marsh intercepts most of the groundwater DIN (mostly nitrate) during winter and spring. This may be due to the conversion of nitrate dissolved in the water into nitrogen gas by denitrifying organisms, described later. During midsummer the marsh imports DIN, as the grasses take up ammonium during maximum growth. With the onset of senescence, plant leaching and decay lead to export of DIN. The coming of winter slows all these processes. Throughout most of the year the marsh intercepts DIN (principally nitrate) that otherwise would flow into deeper waters.

Denitrification. In low and high marsh—habitats where plant roots consolidate sediments—rates of denitrification were measured using a bell jar method. Darkened glass bell jars were pushed about 20 cm into the sediment and the headspace was flushed with helium. Argon was injected into the headspace as an internal standard. After a 4-h incubation, samples of the gas in the headspace were removed and the ratio of nitrogen-to-argon was measured by gas chromatography.

The denitrification rates of the wet flocculent sediment of creek bottoms and pannes were assayed using a gas-partitioning technique. Samples of the sediment were placed in serum vials and flushed with helium. After incubation for 24 h the gas in the sediment was stripped onto the headspace by shaking. The gases were then sampled and analysed by gas chromatography[20].

The rates of denitrification were measured monthly at each of the habitats (Fig. 2). Due to the higher rates (maximum of 5 mg N m^{-2} h^{-1}) and large area of creek bottoms[20], this habitat was the site of over 50% of the net denitrification for the marsh. The low marsh had peak denitrification rates of 2–3 mg N m^{-2} h^{-1}, while the high marsh rates were only ~1 mg N m^{-2} h^{-1}. The rates in the pannes reached over 5 mg N m^{-2} h^{-1} but their small surface area did not make a large contribution to losses of N from the marsh as a whole. In the algal mats the high fixation rates were matched by high rates of denitrification[20]. In all habitats there was a strong seasonal pattern associated with the annual temperature cycle.

Both techniques used to measure denitrification yield results that represent the difference between true denitrification rates and simultaneous nitrogen fixation within the sediment. In Table 1 we added the measured amounts of nitrogen fixed to the amount of nitrogen lost by denitrification to obtain the total amount denitrified. This rate of total denitrification shows that low marsh and creek bottoms are the habitats where denitrifiers are most active and contributed the most to losses of N by denitrification (Fig. 2). The other habitats are of minor importance and the whole marsh exports about 6,940 kg N yr^{-1} as nitrogen gas.

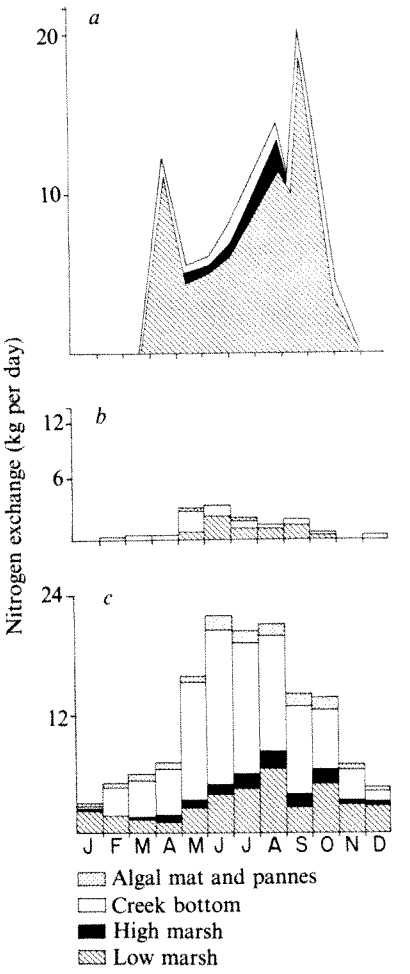

Fig. 2 Nitrogen exchanged by microbial processes in Great Sippewissett Marsh. Each major habitat is shown separately. Values are the products of rates × areas of each of the habitats. *a*, Bacterial N_2 fixation; *b*, algal N_2 fixation; *c*, denitrification.

Nitrate is not exported during the spring and summer. This is the time of year when rates of denitrification are highest, suggesting that denitrifiers are active enough to substantially alter the chemistry of tidal water.

Losses to sediments. The rate of accretion of sediments was obtained from measurements made for marshes near Great Sippewissett[21,22]. For well-established vegetated zones, we used a value of 0.15 cm yr^{-1} as the rate of sediment accumulation. In sediments of Great Sippewissett Marsh there is an average of

1.4% N and the specific gravity of 0.2 g dry weight cm^{-3}. We estimate that in the area stabilised by the growth of vegetation (302,900 m^2), 1295 kg N yr^{-1} is lost to the sediments. Although the loss of nitrogen to sediments is substantial relative to other inputs and outputs (Table 1), the amount of nitrogen sedimented is only about 1% of the estimated 116,800 kg N stored in the top 15 cm of marsh sediments. The bulk of the roots of marsh plants are found above a depth of 15 cm (ref. 23) and therefore any nitrogen found above 15 cm could be potentially recirculated by plant uptake. We are concerned here with losses that occur when nitrogen is left below a depth of 15–20 cm as the marsh peat accumulates.

Minor sources and losses. Our value for the amount of nitrogen lost from Great Sippewissett Marsh through volatilisation of NH_3 is based on rates measured in North Carolina[24]. At the range of *p*H values (5–8) measured in our marsh sediments, volatilisation would be small (Table 1).

Flocks of gulls use the marsh as a roost. As they feed largely elsewhere, we consider their defaecation to be an input of nitrogen. We calculated this small input (Table 1) by noting the average number of birds in the marsh, the average defaecations per unit time and the weight and per cent of nitrogen in the faeces.

There is active shellfishing in Great Sippewissett Marsh. The removal of nitrogen by this pathway was estimated by using the records kept by the shellfish warden and the per cent nitrogen in the shellfish meats. This is also a small figure (Table 1).

The balance sheets

Table 1 summarises annual nitrogen transport. The sum of the inputs is remarkably close to the sum of the outputs (only about 11% difference). This balance would be required for long-term persistence of an ecosystem in its present state.

Although adequate replication and estimates of variation for each process are available[12,16,18,20], as only one marsh was studied the variability for each entry in Table 1 cannot be easily estimated. There is the further problem that even very small errors in, for example, rates of flow of tidal water may be more important than larger errors in measurements of nutrient concentrations. This is inherent in the arithmetic used in making the estimates of Table 1. From our experience and by pooling estimates of variation from the data available[12,16,18,20], we believe that the coefficient of variation of each entry of Table 1 would be about 20% of the mean. Thus, the small 11% variation between inputs and outputs of Table 1 is fortuitous. This agreement suggests that major parts of the nitrogen budget have been accounted for.

Does the marsh have much flexibility to adjust to increased eutrophication of ground and tidal waters? Of the total nitrogen budget of Great Sippewissett Marsh, 91% of the inputs and 83% of the outputs were driven by physical forces which might indicate little room for adjustment. However, if the refractory (see below) dissolved organic nitrogen is not considered, less than 50% of the exchanges are purely physical and the possibility of considerable biological adjustment may be indicated. As dissolved ammonium increases, nitrogen fixation is sharply curtailed[25]. Fixation amounts to 9 or 20% of the input, again depending on whether or not the DON is considered an inert fraction of the nitrogen budget. In either case this biological feedback system can make only a relatively small change in the system's ability to handle increased nitrogen inputs. Perhaps increased rates of denitrification with increased supply of nitrogen can also serve as a feedback mechanism for adjusting nitrogen flow through the marsh. Our evidence is not conclusive[26], although others have shown increased denitrification after nitrate enrichment[27]. To be effective, increases would have to be large and our rates are already among the higher values reported[20]. Salt marsh sediments show very large rates of sulphate reduction[28]. As nitrate is energetically more favourable as an electron acceptor than sulphate, large increases in nitrate reduction are possible if new supplies of nitrate are made available.

Internal mechanisms, nevertheless, are unlikely to regulate the amount of nitrogen entering salt marshes. Eutrophication of entering fresh and tidal waters will probably result in an increase of the nitrogen pool within the marsh, especially in sediments and vegetation. This will to some extent enhance primary production in salt marshes[2–5]. Human contamination affects principally ground and tidal water, the two largest processes providing nitrogen to the marsh. Of the two, contamination of groundwater may be more important as flow is one way into the marsh and, at least in North America, disposal of sewerage wastes is conducted primarily by leaching wastewater through cesspools and septic tanks into the soil. This may result in enhanced concentrations of nutrients, particularly nitrate, in groundwater throughout the coastal zone.

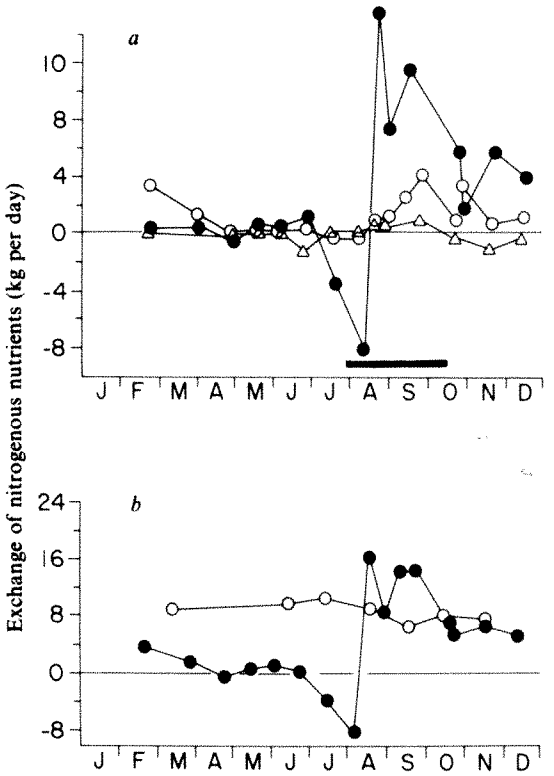

Fig. 3 Exchanges of nitrogenous nutrients between Great Sippewissett Marsh and Buzzards Bay through the year. In *a*, points are net exchanges for a given tidal cycle and recalculated in units of kg per day. ●, NH_4—N; ○, NO_3—N; △, NO_2—N. The solid bar shows the flowering season for *Spartina alterniflora*. *b*, Compares net tidal exchanges of dissolved inorganic nitrogen (●) with the dissolved inorganic nitrogen furnished by groundwater (○) flowing into the marsh. Values in both graphs above the 0 in the *y* intercept are net exports from Great Sippewissett Marsh, while negative values show an import into the marsh.

A better view of the action of a salt marsh ecosystem as a transformer of chemical forms of nitrogen can be obtained by rearranging the entries of the nitrogen budget. The annual exchanges of the major forms of nitrogen for Great Sippewissett Marsh are shown in Table 2. Sixty-four percent of the nitrogen entering the marsh as nitrate is intercepted by the marsh. The oxidised nitrogen imported into the marsh is reduced to various forms within the marsh. Ultimately most of the entering nitrogen is exported by tidal water in the form of particulate, ammonium and molecular nitrogen.

These exports are substantial. Export of dissolved inorganic nitrogen from the area of marshland around Buzzards Bay at a rate comparable to that found in Great Sippewissett Marsh in

Table 2 Annual exchanges of major forms of nitrogen for Great Sippewissett Marsh (kg yr^{-1})

Form of N	Input	Output	Net	% of input
NO_3—N	3,420	1,220	2,200	64
NH_4—N	3,150	3,550	−400	−13
DON	19,200	18,500	700	4
Particulate N	6,750	8,200	−1,460	−22
N_2	3,280	6,940	−3,660	−112
Totals	35,800	38,410	−2,610	−7

The exchanges of nitrite and the nitrogen lost to the sediments are not included.

August could entirely replace the nitrate content of Buzzards Bay in 100 days[12]. The amount of particulate organic matter exported yearly from the marsh is equivalent to about 40% of the net annual above ground production of the marsh[12]. As salt marshes are among the most productive ecosystems on a per unit area basis, these amounts exported are quantitatively significant and must be important to detritus feeders in coastal waters.

As annual denitrification rates exceed fixation, there are large losses of nitrogen from the marsh as N_2 gas. This is the second major pathway of nitrogen export.

The large amounts of dissolved organic nitrogen (Tables 1, 2) are mostly unaffected by passage through the marsh. This agrees with other results that suggest that the bulk of DON is refractory to microbial attack[29], although DON is the principal form of nitrogen in terms of total amounts.

Approximately 6,940 kg of nitrate nitrogen are required to supply the marsh denitrification annually. This is a larger amount than is available through the net import of nitrate (2,200 kg yr^{-1}, Table 2). This means that some nitrification of ammonium must take place within the sediments.

The amount of ammonium entering the marsh is composed of three sources; (1) net exchange by tides, groundwater and rain (1,450 kg N yr^{-1}); (2) the small amount of mineralisation of DON (700 kg N yr^{-1}); and (3) the amount fixed by microorganisms (3,280 kg N yr^{-1}). The total of these three sources is 5,430 kg N yr^{-1}. After allowing 1,460 kg N yr^{-1} for export of particulates and 1,295 kg N yr^{-1} for losses to sediments, only 2,675 kg N yr^{-1} are available for use within the marsh. Yet we estimate that growth of marsh plants must use about 8,800 kg N yr^{-1}. Thus, it is clear that very active uptake, release, conversion and recycling of nitrogen must take place within the marsh.

If the salt marsh were not present, Buzzards Bay would receive the nitrate from the groundwater and the phytoplankton would be the principal part of the Bay's ecosystem that would be affected. The marsh intercepts much of this nitrate and exports primarily particulate nitrogen to the sea. This export principally affects the animals that feed on particles, a very different component of the coastal food web. These interactions between marsh and bay maintain the structure of benthic and fish communities in the bay. Similarly, the flow of groundwater structures the marsh biota by providing dissolved inorganic nitrogen for plants and denitrifiers.

These results demonstrate that there are significant interactions among units of landscape, in our case nutrient exchanges among upland, marsh and coastal waters. In view of their importance it is obvious that these interactions among ecosystems have not received enough attention. Many aspects of the structure of an ecosystem, such as what plants, animals or microbes are present, and how many of each kind, are strongly affected by nutrients delivered from outside the particular ecosystem.

Conclusions

Our findings show that there are significant exchanges of nutrients between upland, marsh and coastal waters, and these interactions affect the structure and composition of these systems.

Groundwater often imports more N into salt marshes than does precipitation. Contamination of coastal zone groundwater by sewage is probably important to the marsh nitrogen economy. However, tidal water causes a net export of all nutrients studied, especially ammonium and particulate nitrogen. Quantitatively, tidal exchange is the most important nitrogen transport mechanism. Ammonium export seems to be linked to the activity of marsh grasses, and uptake and leaching are important mechanisms. Nitrogen fixation by bacteria is larger than that by blue-green algae and most bacterial fixation is associated with the roots of marsh grasses.

Dissolved organic nitrogen is the major form of N in the water but little of this is available to decomposers. Despite this rates of denitrification are high. Denitrification may be responsible for the interception by the marsh of the nitrate transported by the flow of groundwater. Annual denitrification for the entire marsh exceeds nitrogen fixed, causing a net export of N_2 to the atmosphere.

Loss of nitrogen to deeper sediments is significant, but this is small in proportion to the nitrogen pool found in the surface sediments where plant roots are found.

The amount of dissolved inorganic nitrogen required to satisfy growth of higher plants and supply the nitrate for denitrification is larger than imports of DIN, which suggests that nitrification, nitrogen fixation and active recycling of N are all important within the marsh. Nitrogen export by the marsh is also important for coastal waters and the transformation of oxidised imports to reduced exports is significant to the coastal ecosystems that receive marsh exports.

Altogether, the imports and exports of nitrogen are in balance. This, along with other evidence, suggests that an old salt marsh such as that studied is in a long-term steady state. Young marshes may be traps for sediment and particulate nutrients suspended in tidal water, but this becomes less marked as the marsh develops, with mature marshes exporting particulates.

We thank S. Volkmann, D. Shafer, C. Van Raalte, W. Kaplan, N. Butler, E. Carpenter, C. Cogswell, D. Berlo, S. Mlodzinska, P. Clarner and P. Glibert for their contributions, Charles Hall, John Hobbie and G. W. Woodwell for reviews of an earlier version of the manuscript. This research was supported by NSF grants GA 43008 and GA 43009. We are indebted to Salt Pond Sanctuaries and to the late Arnold B. Gifford and his family for permission to use their land on Great Sippewissett Marsh.

Phenotype stabilisation and integration of transferred material in chromosome-mediated gene transfer

L. A. Klobutcher
Department of Human Genetics

F. H. Ruddle
Department of Biology, Yale University, New Haven, Connecticut 06520

The human genes for thymidine kinase, galactokinase and procollagen type I, located on chromosome 17, have been transferred to cultured mouse cells. In unstable cell lines the transferred genetic material is shown to exist independently, whereas in stable cell lines the transferred material has become associated with chromosomes of the recipient cell. The size of the transferred genetic material exceeds 1% of the human haploid genome in some of the transformed cell lines. In addition, the data indicate a gene order of: centromere–galactokinase–(thymidine kinase, procollagen type I), on the long arm of human chromosome 17.

PURIFIED metaphase chromosomes have been used as vectors for the transfer of genetic information between cultured mammalian cells[1-7]. This process, referred to as chromosome-mediated gene transfer (CMGT), typically results in the transfer of subchromosomal amounts of genetic material[2-4]. Expression of the transferred genetic material (transgenome) can be either stable or unstable following return of gene transfer cell lines (transformants) to non-selective culture conditions[1,3,5-7] (for detailed reviews of the CMGT process see refs 8, 9).

To examine the nature of the CMGT process, we have transferred the human chromosome 17 gene thymidine kinase (TK, EC 2.7.1.75) to cultured mouse cells. In some instances co-transfer of the syntenic genes galactokinase[10] (GK, EC 2.7.1.6) and type I procollagen (PCI)[11] was detected. This three-gene segment has provided a means of defining the length of a transgenome and facilitated examination of the fate of the transgenome. In addition, we present data concerning the order of these three genes and assess the usefulness of CMGT as an intergenic mapping procedure. We have also observed donor chromosome fragments and co-transfer of asyntenic genes in some transformants.

Generation and characterisation of primary transformants

Human chromosomes isolated from HeLa S3 (TK^+) cells were applied to the mouse cell line LM(TK^-) which contains a non-reverting ($<10^{-9}$) mutant allele of TK. The CMGT procedure used[3] produced transformed colonies at an overall frequency of 2.3×10^{-7} per recipient cell (Table 1). In control experiments without donor chromosomes no colonies were observed.

Seven independent cell lines, designated TGT, were isolated from two transfer experiments. Two of the transformants, 2TGT2 and 2TGT4, were found to express the human form of GK (Table 2). Human PC I production was assayed by Ouchterlony double immunodiffusion using an antibody to the purified human protein[11]. Of the seven cell lines examined, only 2TGT4 expressed human PC I.

The stability of the transferred phenotype was assayed by cultivating the transformants in non-selective medium and periodically determining the proportion of cells able to form colonies in hypoxanthine, aminopterin and thymidine (HAT) selective medium (see Fig. 2 legend). Transformants TGT1, 2TGT1, 2TGT2 and TGT3 expressed the TK^+ phenotype stably, that is, >90% of the cells remained HAT resistant after 30 d in non-selective medium. Transformants 2TGT4 and 2TGT5 were unstable, losing the HAT-resistant phenotype with first order kinetics at a rate of 2.5% per cell generation. The remaining transformant, TGT2, seemed to be a mixture of stable and unstable cells.

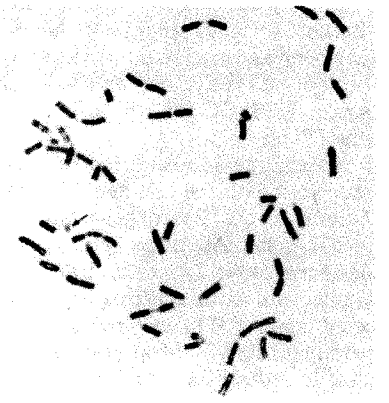

Fig. 1 Alkaline Giemsa[12] stained metaphase spread of transformant 2TGT4 containing an independent human chromosome fragment (arrow). Human chromosomal material appears lightly stained, whereas mouse chromosomes stain darkly, with the exception of their centromeric regions (lightly stained). Twenty metaphase spreads were observed and photographed for each cell line analysed.

Karyotypic analyses of the transformants were carried out using the alkaline Giemsa staining technique[12]. This method produces a differential staining of rodent and human chromosomes and is effective in detecting small amounts of human chromosomal material in a predominantly mouse background. Of the seven transformed cell lines, two possessed detectable human chromosome fragments. Transformant TGT2 contained a large human fragment that was translocated to a

Table 1 Summary of TK transfer experiments

Expt	No. of LM(TK⁻) recipient cells	Cell equiv. of HeLa chromosomes	No. of flasks with colonies	Transfer frequency
1	2×10^7	3×10^7	2/20	1×10^{-7}
2	1×10^7	1×10^7	5/10	5×10^{-7}
3	2×10^7	0×10^7	0/20	0

Mitotic HeLa cells were obtained by treating cultures with 5 atm. nitrous oxide for 18 h. Chromosomes were isolated and applied to LM(TK⁻) cells according to the method of Willecke and Ruddle[3]. Following incubation, recipient cells were diluted with minimal essential medium (αMEM) plus 10% fetal calf serum, and 1×10^6 cells were plated per 75-cm² Corning culture flask. HAT selection was begun 24 h later[24]. Transformed colonies appeared after 2–3 weeks and were expanded for further analysis. All cell lines were negative for mycoplasma contamination by the culture method of Hayflick as modified by Barile *et al.*[25]. For the calculation of transfer frequency, each flask containing colonies was considered as one event, irrespective of the number of colonies present.

mouse chromosome. Transformant 2TGT4 contained an independent human fragment (Fig. 1). This fragment was similar in size to the long arm of human chromosome 17 and possessed a terminally constricted centromere-like region. G-banded chromosome preparations[13] revealed that this chromosome fragment possessed the banding pattern characteristic of the long arm of human chromosome 17. These observations of cytologically detectable chromosome fragments confirm previous work from our laboratory[14]. It now seems that there is a range of transgenome sizes, the largest exceeding 1% of the human haploid genome.

Co-transfer of asyntenic genes

The transformed cell lines were analysed for the expression of 20 additional human isozymes assigned to 16 different human chromosomes[15,16]. Five of the seven transformants were negative for all human isozymes examined. One cell line, TGT2, expressed the human form of adenylate kinase (AK1, EC 2.7.4.3), which has been assigned to human chromosome 9, and another transformant, 2TGT1, expressed human mannose phosphate isomerase (MPI, EC 5.3.1.8), a human chromosome 15 marker enzyme (Table 2).

Two types of experiments indicate that the asyntenic genes have become associated with the selected TK gene. First, nine independent subclones of TGT2 were generated under selective pressure for the TK gene. All these subclones continued to express the human form of AK1. Second, transformed cell lines which had co-transferred both syntenic and asyntenic genes were back-selected against TK by growth in medium with 5-bromodeoxyuridine (Table 2). Mass populations of surviving cells were analysed to reduce the effect of spurious dual segregation events. Back-selectants of transformants 2TGT2 and 2TGT4 lost the linked human chromosome 17 genes concomitant with TK. Similarly, back-selectants of 2TGT1 and TGT2 lost the natively asyntenic genes MPI and AK1. Karyotypic analysis of back-selectants derived from lines containing human chromosome fragments demonstrated loss of the fragments coincident with loss of the transferred markers.

There are at least two mechanisms which could result in the transfer and association of asyntenic genes with selected genes. The HeLa cell line used as the chromosome donor is typical of continuous tissue culture lines in possessing some chromosome rearrangements. Rearrangements involving chromosomes 17, 9 and 15 could have created artificial synteny groups in the donor cell line which were subsequently picked up in the transfer experiments. Alternatively, the CMGT process could cause co-transfer of genuinely asyntenic genes. Transfer of unlinked markers has been observed in bacterial transformation experiments (congression)[17]. Such results are due to the cell's ability to ingest and express more than one piece of DNA. Mammalian cells are capable of ingesting more than one chromosome in CMGT conditions[18]. Uptake of more than one chromosome followed by partial degradation and reconstruction could explain co-transfer of asyntenic genes.

In other CMGT experiments we have observed five additional transformants expressing normally asyntenic genes (our unpublished results with Miller and Church). The first mechanism proposed would require extensive rearrangement of the HeLa karyotype to explain these results. As the HeLa cell line is basically triploid with a minimal number of rearrangements[19], we favour the second hypothesis. A rigorous test of the hypothesis will require transfer experiments using a primary cell line with a normal diploid karyotype as the chromosome donor. Such experiments are in progress.

The unstable transgenome and its conversion to stability

Various experiments have indicated that the transgenome in stable transformants has become associated with chromosomes

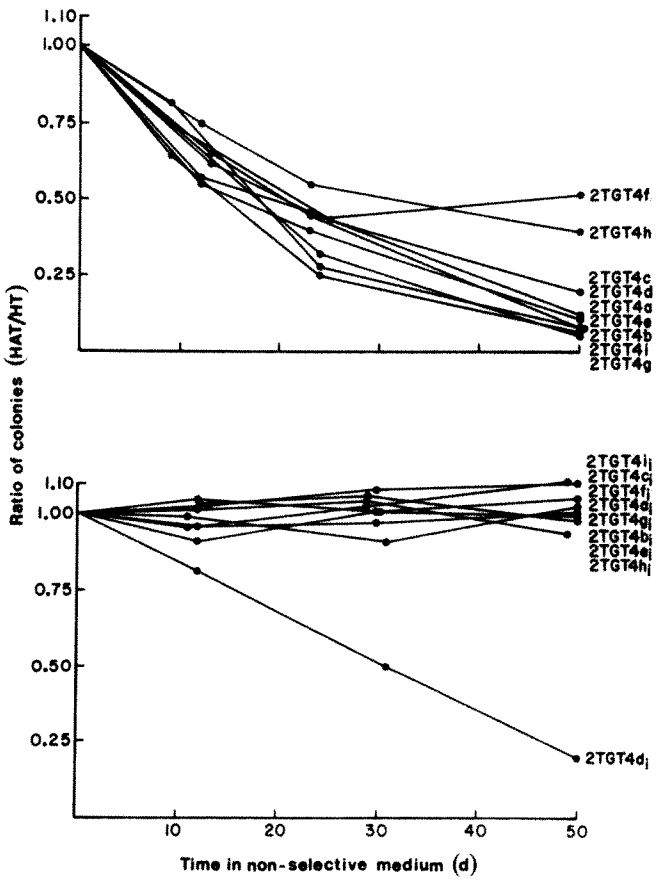

Fig. 2 Stability analyses of subclones of the 2TGT4 transformed cell line. *a*, Stability analyses of nine primary subclones, 2TGT4a–2TGT4i, of transformant 2TGT4. *b*, Second stability analyses of the nine subclones following their growth in non-selective medium for 75 d, and an additional period of growth with HAT-selective medium for 14 d. Eight of the nine subclones now stably express the transferred phenotype. Stability analyses were carried out by culturing transformed cell lines in non-selective medium for at least 30 d. At various times, 200 cells were plated in duplicate flasks with either HAT-selective medium or non-selective HT medium (medium supplemented with 0.1 mM hypoxanthine and 0.016 mM thymidine). After 9–10 d the resulting colonies were stained with 0.25% Wright's stain in methanol and counted. The number of colonies formed in HAT as against HT medium is taken as a measure of the fraction of cells retaining the transferred (TK⁺) phenotype.

of the recipient cell[20–23]. The precise nature of this association remains unclear. Even less is known about the state of the transgenome in unstable transformants. Prolonged culture in selective medium, however, often results in conversion from unstable to stable expression[5,7]. It has been postulated that stabilisation occurs infrequently as a unique event in a single cell. The resulting stable cell would thus acquire a growth advantage while in selective medium due to its ability to distribute the transgenome efficiently to daughter cells. Stable cells would then gradually overgrow the unstable cells, giving rise to a completely stable population.

Transformant 2TGT4, which expresses all three human chromosome 17 genes and contains a detectable human chromosome fragment, was chosen for investigating the nature of the unstable transgenome and its conversion to stability. Nine independent subclones (2TGT4a to 2TGT4i) of transformant 2TGT4 were derived and analysed for stability (Fig. 2). Six of the subclones were completely unstable, as more than 90% of the cells lost the HAT-resistance phenotype after 50 d of growth on non-selective medium. Subclones 2TGT4c, 2TGT4f and 2TGT4h did not meet this criterion for unstable expression and will be discussed separately. Each of the six unstable subclones continued to express human GK and PC I. Karyotypic analyses of each of these cell lines revealed a single human chromosome fragment indistinguishable from the fragment present in the 2TGT4 cell line. Thus, the unstable transgenome is an independent and constant entity, losing no genetic information and undergoing no gross structural changes.

Table 2 Summary of TK transformed cell lines

Cell line	TK	GK	PC I	AK1	MPI	Stability	Detectable human chromosomal material
Primary transformants:							
TGT1	+	−	−	−	−	S	−
TGT2	+	−	−	+	−	Mixed	+
2TGT1	+	−	−	−	+	S	−
2TGT2	+	+	−	−	−	S	−
2TGT3	+	−	−	−	−	S	−
2TGT4	+	+	+	−	−	U	+
2TGT5	+	−	−	−	−	U	−
Back-selected transformants:							
TGT2BS	−	ND	ND	−	−	ND	−
2TGT1BS	−	ND	ND	−	−	ND	ND
2TGT2BS	−	−	ND	ND	ND	ND	ND
2TGT4BS	−	−	−	ND	ND	ND	−

Human PC I expression was assayed by Ouchterlony double immunodiffusion using an antibody raised against purified human type I procollagen[11]. Human GK activity was detected by the starch gel electrophoretic method of Nichols *et al.*[26]. In addition to human AK1 and MPI, all transformants were assayed for the expression of 18 other human isozymes[15]. Back selection of primary transformed cell lines was carried out by growing cells in 30 $\mu g\ ml^{-1}$ of 5-bromodeoxyuridine for 24 h. Culture medium was then removed and replaced with phosphate-buffered saline and the cultures exposed to long-wave UV light for 30 min. The cells were returned to growth in culture medium with 5-bromodeoxyuridine, and mass populations of surviving cells were analysed as back-selectants. +, Expression of human phenotype; −, expression of human phenotype not detected; U, unstable expression of transferred phenotype; S, stable expression of transferred phenotype; ND, not determined.

To study the conversion to stability, we isolated stable derivatives of the 2TGT4 subclones. Each of the nine subclones was grown on non-selective medium for 75 d to remove most unstable HAT-resistant cells from the population, and then returned to HAT-selective medium for 14 d to select and fix any pre-existing, small subpopulation of stable cells. The cell populations carried through this regime (designated 2TGT4a_i to 2TGT4i_i) were again analysed for stability (Fig. 2). All the cell lines, with the exception of 2TGT4d_i, then expressed the transferred phenotype stably. Although all eight stable subclones continued to express human PC I, three of the cell lines no longer expressed human GK (Fig. 3). Karyotypic examination revealed that the human chromosome fragment had become associated with a mouse chromosome in all the stable subclones (Fig. 3). In each subclone the fragment was associated with a single mouse chromosome, but the mouse chromosome involved differed between cell lines. The rearrangements appeared either as centric fusions or terminal additions. When metaphase spreads were stained with the fluorescent dye, Hoechst 33258, each of the centric fusion type chromosomes had the brightly fluorescent centromeric region characteristic of mouse centromeric heterochromatin[13]. Neither the independent human fragment in transformant 2TGT4 nor any of its unstable subclones displayed centromeric fluorescence. These observations indicate that the mouse centromeric region has been retained during stabilisation.

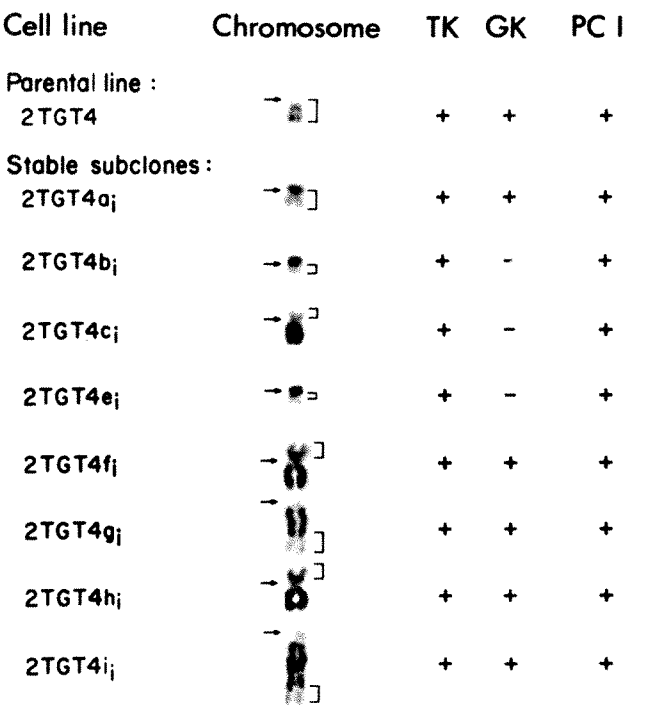

Fig. 3 Expression of human chromosome 17 genes and fate of the human chromosome fragment in the stabilised subclones of transformant 2TGT4. In each case the lightly stained human fragment, indicated by the bracket, has become associated with a darkly stained mouse chromosome. The human chromosome fragment has apparently been translocated to either a mouse chromosome's centromeric region (2TGT4a_i, 2TGT4b_i, 2TGT4c_i, 2TGT4e_i, 2TGT4f_i and 2TGT4h_i) or to the distal portion of a mouse chromosome (2TGT4g_i and 2TGT4i_i). Centromeric regions are identified by the arrows.

Finally, if stabilisation originates in a single cell which then gradually overgrows the population, it should be possible to find cell populations which transiently contain both stable and unstable cells. During a stability test a mixed population would be expected to display a plateau at the frequency of stable cells in the population. The cell lines 2TGT4c, 2TGT4f and 2TGT4h seem to be mixed populations, as they displayed plateaus at 16%, 40% and 50% HAT-resistant cells, respectively (Fig. 2). Karyotypic analysis of these subclones supported this hypothesis. Two types of human chromosome fragment were observed in each of these cell lines. One subset of cells contained the independent human fragment, and a second subset contained the human fragment translocated to a mouse chromosome. The frequency of cells containing the translocated chromosome was similar to the stability test plateau frequency for each cell line. Translocation chromosomes were found in

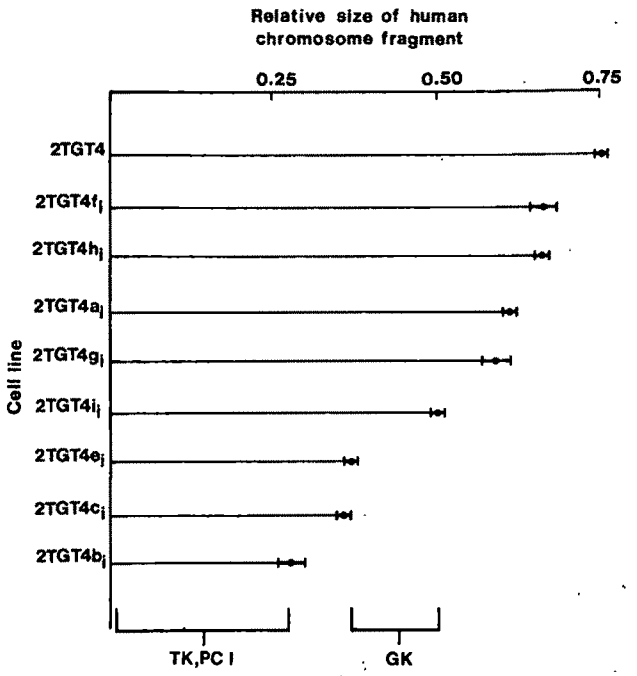

Fig. 4 Histogram displaying the sizes of the human fragments present in the transformed cell line 2TGT4 and its eight stabilised subclones. Relative size values were determined by measuring both the human chromosome fragment and the long arm of a mouse marker chromosome in each metaphase spread. By taking the ratio of the size of the human fragment to the size of the marker chromosome a relative size value was obtained which corrects for variable condensation between metaphase spreads. An average size value was obtained from measurement of at least five metaphase spreads for each cell line. The bars represent ±1 s.e.m. The regions containing the genes for TK, GK and PC I are indicated at the base of the histogram (see text).

10%, 25% and 35% of the cells of transformants 2TGT4c, 2TGT4f and 2TGT4h, respectively.

These experiments provide a visual record of the stabilisation process. The association of the transgenome with recipient cell chromosomes may be viewed as the acquisition of host centromeric activity, ensuring the orderly distribution of transferred genes at mitosis. Stabilisation does not involve the homologous genetic site in the recipient, as the transgenome is shown to associate with several recipient cell chromosomes. These results agree with those of previous studies[22,23]. The earlier studies, however, did not rule out the possibility of multiple sites of association within a single cell. We have shown here that each stable cell contains only one copy of the transgenome. Moreover, the fact that each stabilised subclone has only one type of chromosome associated with the transgenome, as well as the observation of mixed populations with regard to stability, argues that stabilisation originates in a single cell which then overgrows the population.

Genetic mapping by CMGT

Following stabilisation, three of the 2TGT4 subclones did not express human GK (Fig. 3). Moreover, the length of the human fragment decreased following translocation and was correlated with the number of human genes retained (Fig. 4): the largest fragments were in cell lines retaining all three human chromosome 17 genes, and the smallest were in cell lines retaining only TK and PC I. To examine the nature of the breakage during stabilisation, chromosome preparations were examined by G-banding[13]. All stable transformants, except 2TGT4g$_i$ and 2TGT4i$_i$ which could not be examined by G-banding due to the similarity of the translocation chromosome to other mouse chromosomes, retained the darkly staining terminal band (17q22–17q25) and various amounts of the remainder of the long arm of human chromosome 17. These results suggest that breaks have occurred near the centromere-like end of the fragment during stabilisation. If we assume that stabilisation involves a single break and fusion of the fragment, and not a complex rearrangement, a deletion map is generated. The map indicates a gene order of centromere–GK–(TK, PC I) (Fig. 4). The data do not allow unambiguous determination of the order of TK and PC I, but failure to segregate PC I suggests that it is distal to TK.

Deletion mapping following stabilisation of visible chromosome fragments provides a means of deriving qualitative intergenic mapping data. Alternatively, the co-transfer frequency of non-selected genes in primary transformants may be a source of quantitative intergenic mapping data[5,6,9,14]. Although the number of cell lines analysed here is too small to assess directly the usefulness of CMGT in this regard, two observations indicate that only primary unstable transformants should be used to determine a reproducible co-transfer frequency. First, stabilisation coincides with a decreased transgenome size. The co-transfer frequency of a given gene in a population of stable transformants will therefore be lower than in a population of unstable transformants. Second, the consistent loss of the centromere-like end of the chromosome fragment in the stable subclones of transformant 2TGT4 suggests transgenomes may undergo stabilisation in a polar fashion. Polar effects would differentially influence the co-transfer frequency of genes proximal and distal to the selected gene.

Additional transfer lines will have to be examined to determine how generally applicable these findings are. The ability to generate large numbers of transformed cell lines through recent modifications of the transfer technique[14] will aid in both confirming these results and providing quantitative mapping data. The further development of CMGT as a mapping procedure will provide an intermediate level of mapping resolution between restriction endonuclease analysis and somatic cell hybridisation.

We thank Dr R. Church for carrying out procollagen assays, Ms E. Nichols, Mr D. Laska and Ms S. Pafka for technical assistance, Mrs M. Reger and Mrs M. Siniscalchi for preparation of the manuscript, and Drs R. Fournier, G. Scangos, P. D'Eustachio and D. Plotkin and Ms D. Slate for helpful discussions and critical reading of the manuscript. IUE observations of an active region of HD206860

THE chromospheric Mg II *h* and *k* lines seem to have doubly reversed emission core in the spectra of the Sun and of solar and late type stars. In the solar spectrum the general appearance of Mg II *h* and *k* is very similar to the *H* and *K* of Ca II, but with larger intensity fluctuations. Current ideas suggest that the *h* and *k* lines are strongly sensitive to chromospheric parameters. In quiet areas of the Sun the Mg II emission shows asymmetric doubly reversed profile with a brighter blue peak, while in plages the emission is much stronger and nearly symmetrical[1]. The Mg II doublet seems to be a very useful way of investigating the presence of active regions on stars. We report here the results of our observations of the intensity of the Mg II *h* and *k* lines of the star HD206860 collected with the IUE at the Villafranca Satellite Tracking Station of the European Space Agency (ESA). The aim of the observations was to search for short-term variability of the chromospheric emission connected with the rotation period of the star.

HD206860 is a GOV star with prominent emission cores on the *H* and *K* lines of ionised calcium. Spectrophotometric observations by Wilson[2] show small amplitude but definite variations of the Ca II *H* and *K* emission components indicating activity in the chromosphere of HD206860. No clear long-term periodicity results from Wilson's observations which were carried out between 1966 and 1975. The data show an apparently random scatter much larger than the scatter of the standard stars. Such scatter may be due to fluctuations of the line intensity in a short time scale.

Since the stars with *H* and *K* chromospheric activity seem the most likely to show photospheric activity, HD206860 was included in a wide programme of UBV photoelectric observations of solar type and late-type stars, undertaken at the Catania Astrophysical Observatory to investigate light variations which might be ascribed to spots or more generally to active photospheric regions[3,4]. The analysis of the observations from 1970 to 1977 shows regular small amplitude variations in the light of HD206860. The amplitude in V light is 0.02 m and the period 24.9 d[4,5]. By the hypothesis that the light variations are due to spots on the star surface, the period of 24.9 d must be the rotation period of the star and this is an appropriate value for a GOV star like HD206860[5,6]. However, no correlation of the *H* and *K* line data from Wilson's observations with the 24.9 d period was found.

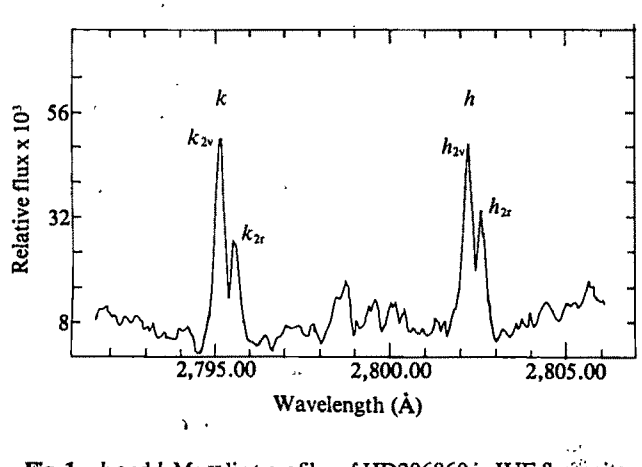

Fig. 1 *h* and *k* Mg II line profiles of HD206860 in IUE flux units. The blue emission component k_{2V} and the red emission component k_{2r} are outstanding.

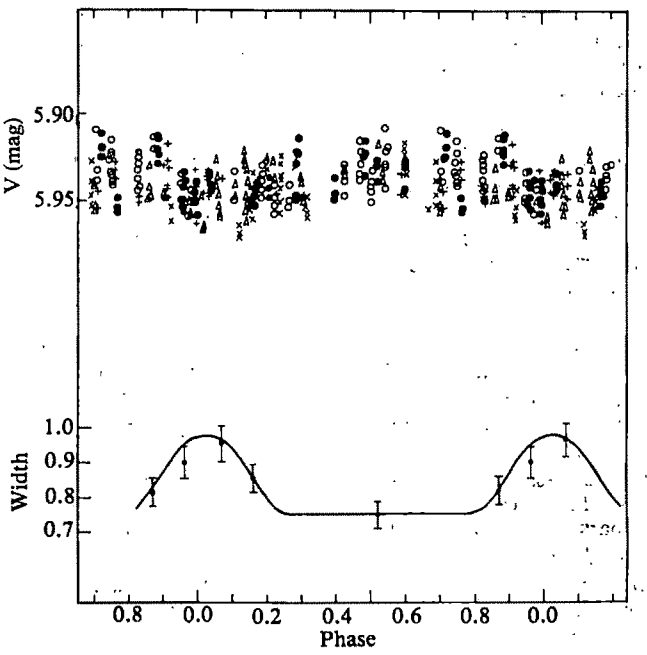

Fig. 2 Photometric observations of HD206860 in V light (different symbols refer to different years of observations) and equivalent width of the *k* emission component of the Mg II versus phases computed with the elements $(JD)_0 = 2440821.48$ and period of 24.9 d.

It is surprising that the Ca II *H* and *K* lines do not correlate with the 24.9 d, even if they show short term variability as deduced from the large random scatter in Wilson's observations. Different intrinsic and observational causes may contribute to the lack of the correlation: (1) the variations of the Ca II lines are less prominent than those of the Mg II ones; (2) Wilson's measurements[2] include photospheric contribution in the line which partially hides the variations of chromospheric origin.

To check these results repeated UV observations of HD206860 were made with the IUE. Five high-resolution spectra (~0.2 Å) in the long wavelength region (λ 1,900–3,200 Å) and two low resolution spectra (~7 Å) in the short wavelength region (λ 1,150–1,900 Å) were obtained from 18 November to 29 December 1978 at the Villafranca Observatory.

In the long wavelength region we concentrated our attention on the emission cores of the Mg II *h* (λ 2,803 Å) and *k* (λ 2,796 Å) resonance lines. A profile of the *k* line in IUE flux units is shown in Fig. 1, where the two emission peaks k_{2V} (the blueshifted component) and k_{2r} (the redshifted component) are evident.

Exposure times (Table 1) have been chosen to produce a well exposed spectrum at the k_2 peak, leading to a signal-to-noise

Table 1 Observational data of HD206860 and measured quantities of the Mg II line referred to the line wing at λ 2,784.5 and λ 2,815

Date (1978)	Exposure time (min)	k_{2V}	k_{2V}/k_{2r}	$(W_k)_E$	φ
18 November	44	1.52	1.77	0.814	0.87
23 November	52	1.60	1.55	0.957	0.07
15 December	52	1.74	1.87	0.899	0.96
20 December	48	1.37	1.41	0.854	0.16
29 December	48	1.41	1.66	0.750	0.52

Equivalent widths of the emission $(W_k)_E$ are in Ångströms. The phases φ are computed with the elements $(JD)_0 = 2440821.48$ and period of 24.9 d.

ratio of about 20. Three or four pixels were satured at the k_2 peak on a few spectra. However, this has little influence on the evaluation of fluxes of the whole Mg II emission.

The output of the IUE software, that is the relative intensity spectrum uncorrected, for the wavelength dependence of the scientific instrument sensitivity has been used to study the change of the k lines of Mg II. To reduce the errors, mainly due to the background subtraction, relevant quantities of the emission profile have been referred to two points of the absorption wings at λ 2,784.5 Å and λ 2,815 Å. Since the line wings can be subject to changes due to the activity a check with the continuum at λ 2,685 Å and λ 2,950 Å was made. This check gave no evidence of such changes of the line wings of HD206860. Intensities at k_{2V} and k_{2r} emission peaks and the equivalent width have been measured on the IUE software plots.

Both the k_2 violet and red peaks were found to vary. The largest changes up to 25% were observed for the violet peak. Also the integrated emission component, that is the equivalent width, shows changes of 25%. Equivalent widths of the k line, measured in Angstrom and referred to the average value of the line wing at λ 2,784.5 Å and λ 2,815 Å, are given in Table 1. The estimated error on the equivalent width is ±5%. A plot of these values using the period and epoch of the photometric variation, given in Fig. 2, shows a fairly defined variation of the line intensity. Although we have only little data, the increase of intensity near the zero phase seems well defined.

A tentative interpretation of these line intensity changes may be given assuming that they result from a localised bright chromospheric active region like a plage. The continuous line in Fig. 2 represents the change of the k line intensity with a complete rotation of the star for an equatorial bright plage covering 10% of the stellar disk and 2.5 times brighter than the quiet chromosphere. A limb darkening coefficient equal to 0.5 was also assumed. The agreement with the observations seems fairly good.

Solar chromospheric faculae show an enhancement of the k (Mg II) line intensity[1] from two to three times the value of the quiet chromosphere, so the value 2.5 assumed in the case of the active region of the solar type star HD206860 seems to be reasonable.

No accurate value of the limb darkening for the solar k Mg II line is given in the literature but the value 0.12 derived from rocket observations[7] seems too small to fit the observed behaviour for the variations of HD206860.

The maximum intensity of the Mg II line seems to occur near the minimum of the V light (Fig. 2). The low accuracy of the photometric period and large time interval involved means that this could be only by chance. However, if this correspondence is real, HD206860 is a good example of a star with solar type activity, that is a photospheric dark spot underlying a bright chromospheric plage. So the variations of the intensity of the k line seem to confirm the rotation period of 24.9 d, first determined from the photoelectric observations.

Light variations attributed to spots are known for binary stars of the RS CVn or BY Dra class[8,9]. From radial velocity observations[10,11] HD206860 does not appear to be binary, it would therefore be the first single star with an active region detected from photometric observations and confirmed by the spectroscopic ones.

The two short-wavelength region spectra show spectral features indicating plasma temperatures hotter than 20,000 K. Important emission lines and temperatures of formation are: C II λ 1,335 (20,000 K), Si IV λ 1,394, 1,403 (80,000 K), He II λ 1,640 (80,000 K), C IV λ 1,549 (10^5 K). No clear changes are evident for these lines in the two spectra. Unfortunately, they were obtained at about the same phase on the Mg II variation, that is, during the increasing branch. It would be very interesting to see if any of these high temperature lines disappears or changes its intensity when the active region is not visible.

We thank all the staff of VILSPA Observatory for their assistance in observing and reducing the data and Dr F. Ciatti from Asiago Observatory for the spectrum of 29 December. This work was supported by a CNR–SAS contract.

Variations of the Sun's radius and temperature due to magnetic buoyancy

LIVINGSTON[1] has recently measured a decrease in the surface temperature of the Sun coincident with increased solar activity. He interpreted the temperature drop as implying a corresponding reduction in luminosity. I point out here that surface cooling could also be due to a radial expansion of the Sun, with no attendant reduction in luminosity. There is a plausible physical mechanism for such an expansion; namely, variations in magnetic buoyancy due to variations in the magnetic flux in the convection zone over the solar cycle.

The solar luminosity L may be expressed in terms of an effective surface temperature T as $L = 4\pi R^2 \sigma T^4$, where R is the solar radius. For constant R, a decrease in T implies a decrease in L. Alternatively, there can be a cooling (or heating) of the surface due to a radial expansion (or contraction) of the Sun with constant L. For small changes ΔT and ΔR with L constant,

$$\frac{\Delta R}{R} = -2\frac{\Delta T}{T} \qquad (1)$$

As $T \sim 6{,}000$ K, a drop in surface temperature of 1 K would correspond to a relative expansion $\Delta R/R \sim 3 \times 10^{-4}$.

The concept of magnetic buoyancy was introduced by Parker[2] and Jensen[3] and is an important ingredient in the solar dynamo. Consider an isolated magnetic flux tube of field strength B in the solar interior. The sum of the gas pressure p_i and the magnetic pressure $p_m = B^2/8\pi$ inside the tube must balance the external gas pressure p_e, so $p_i + p_m = p_e$, and $p_i < p_e$. If the flux tube is in

0028-0836/79/340662—02$01.00
© Macmillan Journals Ltd 1979

thermal equilibrium with its surroundings ($T_i = T_e$), then the density inside the tube is lower than the density of the surroundings ($\rho_i < \rho_e$) and the flux tube is buoyant. Jensen[3] pointed out that, because of the density depression inside a magnetic flux tube, the presence of magnetic flux tubes in the solar interior will cause the volume of the Sun to increase; thus, we would expect the radius of the Sun to vary with the solar cycle, with maximum radius occurring near sunspot maximum. Jensen's suggestion, which has attracted little previous attention, is pursued here.

How much expansion and contraction of the Sun might we expect due to variations in magnetic buoyancy over the solar cycle? A precise estimate would require detailed knowledge of the magnetic field distribution in the convection zone over the solar cycle and a complete calculation of the effect of the magnetic field on the structure of the solar envelope. This is beyond present capabilities, so instead a crude calculation is used to get a very rough estimate. Consider a toroidal flux tube that circles the Sun at spherical radius R_1 and constant latitude ϕ. Let the tube have field strength B and cross-sectional radius a. The mass of gas within the tube is less than would occupy the same volume in the absence of the magnetic field. The difference in densities outside and inside the tube is given by

$$\Delta\rho = \rho_e - \rho_i = (p_e - p_i)/RT_1 = p_m/RT_1$$

where $T_1 = T_e = T_i$ is the temperature of the flux tube and its immediate surroundings. The total mass defect in the tube is equal to the volume of the tube times $\Delta\rho$, or

$$\Delta M = 2\pi R_1 \cos\phi\, \pi a^2 p_m/RT_1$$

Assuming that this mass ΔM is spread over a thin spherical shell of mean radius R_1 and thickness ΔR, then the mass in this shell is given by

$$\Delta M = 4\pi R_1^2 \Delta R \rho_e$$

Equating the two expressions for ΔM gives

$$\frac{\Delta R}{R} = \frac{\pi}{2}\cos\phi\left(\frac{R}{R_1}\right)\left(\frac{a}{R}\right)^2\frac{p_m}{p_e} \qquad (2)$$

This expression gives an estimate of the relative change in radius due to a single toroidal flux tube.

To obtain a numerical estimate we can, for example, use the results of the study by Weiss[4] of magnetic flux tubes in the solar convection zone, based on equipartition of magnetic energy and kinetic energy of convection. Weiss finds that a typical flux tube has a total flux of 4×10^{21} Mx. The radius and field strength of the flux tube vary slowly from 5,000 km and 5,700 G at the bottom of the convection zone to 14,000 km and 600 G at photosphere. The ratio p_m/p_e varies greatly, from 6×10^{-6} at the bottom of the convection zone to 2.8×10^{-1} at the photosphere. Thus, the dominant contribution to ΔR will come from flux tubes near the top of the convection zone. Using values given by Weiss for a and p_m/p_e in equation (2), for R_1/R in the range 0.98–1.0, we obtain values of $\Delta R/R$ in the range $5\times10^{-8}\cos\phi$ to $2\times10^{-4}\cos\phi$. For example, a single flux tube at a depth of 1,000 km at middle latitude gives $\Delta R/R \sim 2\times10^{-5}$. Now, to estimate the change in solar radius with the solar cycle, we need to estimate the difference in total magnetic flux in the upper convection zone between solar maximum and minimum. If we assume that the total magnetic flux emerging at the solar surface is a good indicator of the total flux in the uppermost layers of the convection zone, then observations suggest a difference in total flux of the order 10^{23} Mx between solar maximum and minimum. This is equivalent to some 25 or more of the individual flux tubes discussed above and could imply a relative change in radius $\Delta R/R \sim 5\times10^{-4}$ or more and a corresponding drop in surface temperature of ~1.5 K or more.

Magnetic field strengths in the convection zone may be higher than the equipartition limit used in the estimate above. Indeed, observations[5] have shown that almost all of the magnetic flux in the quiet photosphere is concentrated to strengths of 1,000–2,000 G, well above the equipartition limit, and the theory of Galloway, Proctor and Weiss[6] predicts that magnetic fields will be concentrated to 10 times the equipartition limit or more by the convection. Equation (2) can be rewritten as

$$\frac{\Delta R}{R} = \frac{FB\cos\phi}{16\pi R R_1 p_e}$$

where $F = \pi a^2 B$ is the total magnetic flux in the tube. For a tube of fixed total flux, the relative change in radius is proportional to the magnetic field strength. Thus, higher field strengths in the convection zone would increase the estimate of $\Delta R/R$ for a fixed difference in total flux over the solar cycle. With higher field strengths, flux tubes deeper in the convection zone would contribute significantly to $\Delta R/R$. Although there is uncertainty about magnetic fields in the convection zone, the estimates do suggest that the surface cooling of ~6 K observed by Livingston may be at least partly caused by expansion due to magnetic buoyancy.

The historical record of measurements of the solar radius gives no clear or consistent picture[7–9]. The currently accepted value[10] ($R = 959.63''$ at 1 AU) dates back to 1891 and is subject to correction for irradiation[11]. Variability of R with amplitudes ranging from ~0.05″ to ~2″ and periods of 7, 8, 11 and 22 yr has been reported. Giannuzzi[12], for example, found variations in R with amplitude 0.2–0.5″ and period 22 yr. Meyermann[13] reported variations with total amplitude ~0.15″ ($\Delta R/R \sim 1.5\times10^{-4}$) and period 11 yr with maximum radius occurring very near sunspot maximum; this is in good agreement with the theoretical argument above. Gething[8] finds variations in R with amplitude ~0.1–0.2″, but with no obvious correlation with the solar cycle. Improved measurements of the solar radius over a solar cycle are needed to test the ideas expressed here. Recent improvements[9,14] in the theoretical definition of the solar radius should give a considerable increase in accuracy. Changes in opacity during expansion may affect the visual change in solar radius. Note that the solar oblateness measured by Dicke and Goldenberg[15] ($\Delta R/R \sim 5\times10^{-5}$) and later disputed by Hill and Stebbins[16] is an order of magnitude smaller than the variation in mean radius estimated above. Even if the expansion due to magnetic buoyancy is too small to produce a measurable change in surface temperature, it may still be large enough to show up directly as a change in radius. Accurate monitoring of the solar radius over the solar cycle would give a measure of the variation of total magnetic flux in the convection zone and add to our understanding of the solar dynamo. Measurements of the solar radius from space are particularly desirable.

This research was supported by grants from the US Air Force Geophysics Laboratory and NASA. I thank Alfred Clark, Jr and Eugene Parker for helpful comments.

Silicalite-2, a silica analogue of the aluminosilicate zeolite ZSM-11

THE structure of silicalite, a new polymorph of silica which was first prepared by Flanigen *et al.*[1], is so similar to that of the silica-rich aluminosilicate zeolite ZSM-5 (ref. 2) that we suggest that it should be regarded as the aluminium-free end member of this zeolite series. Therefore it should be possible to prepare silica analogues of other silica-rich aluminosilicate zeolites such as ZSM-11 (ref. 3), ZSM-12 (ref. 4), ZSM-21 (ref. 5) and ZSM-34 (ref. 6). We report here the preparation of what we believe is the analogue of ZSM-11, which we call silicalite-2, adopting the terminology silicalite-1 for the form prepared by Flanigen *et al.*[1]. The silicalite-1, ZSM-5, ZSM-11 and, by inference, silicalite-2 frameworks contain 4-, 5- and 6-membered rings linked to form a system of channels with 10-membered ring openings[1-3]. In silicalite-1 and ZSM-5 the channels are a combination of linear and zig-zag[1,2], while in ZSM-11[3] and silicalite-2 all the channels are linear. The lack of substitutional aluminium results in silicalites having no significant catalytic or cation exchange properties compared with the zeolites. However, silicalites are unusual in that they are the only known hydrophobic forms of silica and are capable of absorbing organic molecules up to ~6 Å kinetic diameter. Thermogravimetric studies of silicalites-1 and -2 containing absorbed long straight-chain hydrocarbon compounds (C_4–C_{16}) show that degassing occurs in two stages, which we consider to be due to self-blocking of the channels at intersection points.

The precursors of the silicalites are prepared by reacting tetraalkylammonium or tetraalkylphosphonium salts with a reactive form of silica at a high *p*H, at temperatures between 100 °C and 200 °C, in a closed system[4,5]. We have found that the silicalite-2 precursor can be prepared using tetra-*n* -butylammonium hydroxide only, although adding ammonium hydroxide or hydrazine hydrate as a source of extra hydroxyl ions increases the reaction rate considerably. A successful preparation was to mix 8.5 mol SiO_2 as silicic acid (74% SiO_2), 1.0 mol tetra-*n*-butylammonium hydroxide, 3.0 mol NH_4OH and 100 mol water in a steel bomb and heat at 170 °C for 3 days. The precursor crystals are ovate in shape, ~2–3 μm long and 1–1.5 μm diameter, similar to those reported for ZSM-11[3]. The silicalite-2 precursor will not form if Li, Na, K, Rb or Cs ions are present, in which case the silicalite-1 precursor is formed. The size of the tetraalkylammonium ion seems critical because replacement of the tetra-*n*-butylammonium hydroxide by other quaternary ammonium hydroxides (such as tetraethyl, tetrapropyl, triethylpropyl, and triethylbutyl hydroxides) results in amorphous products. Silicalite-2 precursor is stable at extended reaction times in the hydrothermal system. However, in similar conditions the silicalite-1 precursor converts to α-quartz, presumably due to the effect of alkali metal ions. The amount of Al present in silicalite-2 depends on the purity of the starting materials. We typically find <5 p.p.m. Al present. The precursor contains occluded tetraalkylammonium salts which, because of their size, can be removed only by thermal decomposition. We have observed, by means of thermal analysis and mass spectrometry, that the tetraalkylammonium ion decomposes at ~300 °C and is lost as the tertiary amine, alkene and water. This can be contrasted to the normal thermal decomposition at 200 °C of the same tetraalkylammonium salt in air.

Figure 1 shows the X-ray powder diffraction patterns we have obtained for silicalite-1 and silicalite-2, and for ZSM-5 and ZSM-11. Major differences between the patterns of silicalite-1 and silicalite-2 are that peaks at 9.06, 13.9, 15.5, 16.5, 20.8, 21.7, 22.1, 24.4, 26.6 and 27.0 degrees 2θ (CuKα radiation) are absent from the silicalite-2 pattern. Also, peaks at 8.8, 14.8, 17.6, 23.1, 23.9 and 29.9 degrees 2θ are singlets in the silicalite-2 pattern rather than doublets as in the silicalite-1 pattern. These differences are the same as those found between the diffraction patterns of orthorhombic ZSM-5 and tetragonal ZSM-11. Unit cell dimensions are given in Table 1 calculated on the assumption of tetragonal symmetry for silicalite-2, and show that the effect of the substituted aluminium in ZSM-5 and ZSM-11 is to increase the unit cell size over that of silicalite-1 and silicalite-2. The measured densities and refractive indices of silicalite-2 and its precursor are 1.82 and 1.98 g cm^{-3} and 1.41 and 1.48 respectively. Calculation of the unit cell volumes shows that silicalite-2 should be ~1% less dense than silicalite-1, whereas we find that silicalite-2 is ~3% more dense. The samples of silicalite-2 prepared here possibly contain a small percentage of another 'more dense' crystallographic form of silica.

Desorption or degassing of various organic molecules from silicalite-1 and silicalite-2 has been studied by thermogravimetric analysis. Rigid molecules, such as *p*-xylene, are lost in a single low-temperature step due to simple desorption. However, flexible molecules, such as *n*-alkanes or *n*-alcohols of chain length >C_5 are lost in two steps (Fig. 2). We believe this shows that self-blocking of the channel structure is occurring, probably by molecules bending through 90° into an intersecting channel,

Table 1 Lattice constants

	a	*b*	*c*
Silicalite-1	20.07 (1)	19.86 (1)	13.36 (1)
ZSM-5[2]	20.1	19.9	13.4
Silicalite-2	20.04 (1)	20.04 (1)	13.38 (1)
ZSM-11[3]	20.12	20.12	13.44

and thus preventing egress of other molecules from both of the channels. A higher activation energy is required to overcome the awkward passage of these molecules, resulting in a higher temperature for weight loss when compared with desorption straight through the channel system. Initial results show that there is less self-blocking in silicalite-2 than in silicalite-1. Presumably the zig-zag channels in silicalite-1 are more prone to self-blocking since molecules are required to change direction even when continuing along the same channel, thus increasing the probability of bending into an intersecting channel.

Extraction of uranium from seawater by polymer-bound macrocyclic hexaketone

THE energy crisis means that a petroleum substitute is urgently needed and a promising candidate is nuclear energy. Uranium, however, like petroleum, is distributed in small limited areas. These circumstances could be dramatically improved if uranium in seawater were to be utilised as a resource. Although its concentration is extremely low (3.3 parts per 10^9), the total amount is huge, calculated at $4–4.5 \times 10^9$ tons. We have recently synthesised a macrocyclic hexaketone (I) which is a very strong host of uranyl (UO_2^{2+}) ion[1]. Its noteworthy characteristics are: (1) six oxygen atoms can be directed towards the inside of the ring, if necessary, to form hexadentate coordination in near coplanarity which corresponds to the crystalline structure of various uranyl salts[2,3]. (2) β-Diketone can easily be dissociated in seawater (pK_a is 8.95 for acetylacetone) to form a strong ligand, ketoenolate anion[4]. (3) The bound uranyl ion is readily liberated by the treatment with dilute aqueous acid. Here we report the successful extraction of uranyl ion directly from seawater using polymer-bound macrocyclic hexaketone.

The hexaketone (170 mg, 0.4 mmol) was treated with partially chloromethylated polystyrene (chloromethyl content: 18.8%, 82 mg, 0.14 mmol equiv. for CH_2Cl unit) in dimethylformamide (1 ml) in the presence of anhydrous potassium carbonate (138 mg, 1.0 mmol). An IR spectrum of the resulting polymer, after the usual purification, showed that the CH_2Cl absorption had almost disappeared and new absorptions at 1,720 and 1,600 cm^{-1} had appeared which correspond to keto and enol forms of hexaketone unit.

I II

Polymer-bound hexaketone (II) (98 mg, 0.1 mmol equiv. of (I)) dissolved in chloroform (30 ml) was stirred magnetically with 3.5 l of seawater sampled at 20 m off the coast of Ohara, Sotoboh, Chiba Prefecture, Japan (Fig. 2). After 18 h, a chloroform solution was separated and seawater was extracted with chloroform (5 ml × 2) to recover any dissolved polymer and/or polymer–uranyl complexes. From the combined chloroform solution, uranyl ion was liberated by the treatment with 1 M HCl solution (5 ml)[1]. The resulting acid solution was analysed by the arsenazo III method[5], showing that 0.84 p.p.m. of uranyl ion is present which corresponds to 36% of the UO_2^{2+} present in the original seawater. An independent analysis of UO_2^{2+} by atomic absorption spectrophotometry was also made to demonstrate the presence of approximately the same amount of uranyl ion. Repeated (three times) extraction and liberation of uranyl ion using the recovered hexaketone (II), accumulated 1.5 p.p.m. of UO_2^{2+} in 9.2 ml of acid solution (13.8 μg) (total seawater treated is 3 × 5 l). After these cycles, the same procedure using the hexaketone (II) recovered, was repeated to extract 11 μg of UO_2^{2+} from further 3 × 5 l of sea water. This demonstrated that the recovery and regeneration of hexaketone (II) was satisfactory. The extraction time was then reduced to 1 h and gave practically the same efficiency. These results clearly indicate that the polymer-bound hexaketone (II) can successfully extract uranyl ion directly from seawater and be liberated in concentrated form on treating with a dilute aqueous acid solution.

Attempts to extract uranium from seawater have so far concentrated on the method using the adsorbent hydrous titania sorber[6]. However, economical and environmental analyses are discouraging at present; the major problem is the large loss of titania sorber. It has been estimated that 68 pounds are needed to produce 1 pound of uranium[7]. The method described here avoids an appreciable loss of adsorbent by cross linking the supporting material via chemical bonding, and on further refinements it will give adsorbents specific to uranyl ion. The present procedure, however, is still not practical because the polystyrene backbone is too hydrophobic to achieve an efficient rapid contact with seawater if used in powdered form, although slow extraction does take place. In our preliminary experiments using powder of a partially sulphonated polystyrene, however,

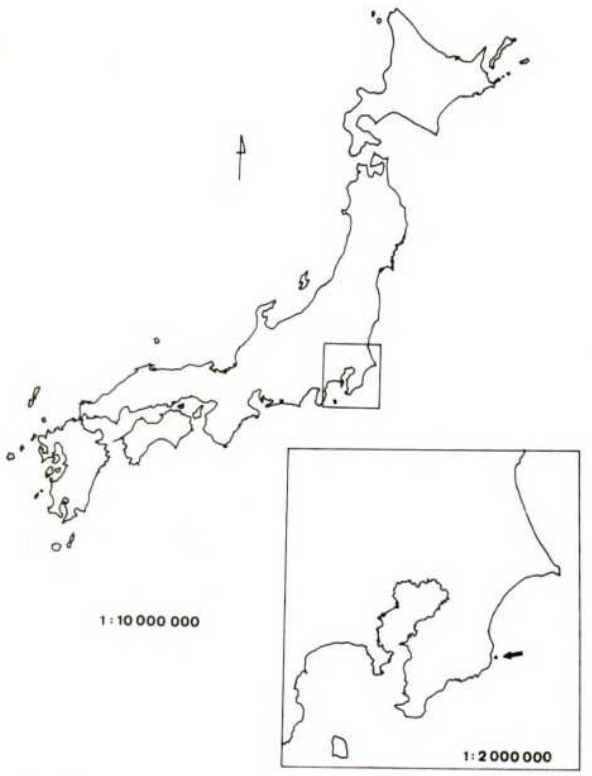

Fig. 2 Seawater was sampled at the spot asterisked along the Black Current.

uranyl ion was very effectively and rapidly extracted from seawater. The polystyrene was partially sulphonated by chlorosulphonic acid followed by the partial chloromethylation. Hexaketone was then attached to this polymer as described above. The details will be published elsewhere.

We thank Idemitsu Kosan Co. Ltd. for the supply of seawater.

Anodic coal reaction lowers energy consumption of metal electrowinning

THE metals which can be extracted in large amounts from aqueous solutions of their salts by electrowinning are Cr, Mn, Co, Ni, Cu, Zn, Ga, Cd, In and Tl. Gilroy[1] specifies an annual electrowinning production for 1971 of 2,400,000 tons of Zn and 540,000 tons of Ca, 53% and 10% respectively of total production at that time. We describe here a modification to the established electrowinning technique which lowers the energy consumption of the process.

Table 1 Current efficiency and electrical energy consumption during copper deposition in the conventional process

Reaction rate I (mA)	Total coulomb consumed It (C)	Theoretical Cu equivalent to the charge passed W_1 (g)	Measured amount of Cu deposited W_2 (g)	Current efficiency $(W_2/W_1) \times 100$ (%)	Electrical power consumed $E_1 = (I\int V\,dt)/W_2$ (kWh kg^{-1})
5.90	100.79	0.03319	0.03027	91.2	1.52
7.95	147.39	0.04853	0.04620	95.2	1.51
10.00	144.00	0.04741	0.04425	93.3	1.52
12.00	133.90	0.0442	1.04288	97.2	1.622

Electrolyte, 0.125 M $CuSO_4$ and 0.5 M H_2SO_4; Temperature, 60 °C.

The reactions for conventional electrowinning of a metal M are:

Anodic: $$X\mathrm{H_2O} \rightarrow \tfrac{1}{2}X\mathrm{O_2} + 2X\mathrm{H^+_{aq}} + 2X\mathrm{e^-} \quad (1)$$

Cathodic: $$\mathrm{M^{2x+}_{aq}} + 2X\mathrm{e^-} \rightarrow \mathrm{M} \quad (2)$$

The reversible thermodynamic potential, $E°$, of reaction (1) is 1.229 V. It and associated polarisation overpotentials, E_{op}, constitute a large portion of the total potential E_{tot} of the practical electrowinning cell:

$$E_{tot} = E° + E_{op} + E_m$$

where E_m is the half-cell potential for reducing the metal ion, reaction (2). Browall *et al.*[2] introduced the reducing agent, CO, at the anode to lower the cell potential for electrolytic production of hydrogen. Using coal as the reducing agent, we devised[3–5] a new electrochemical process which converts coal and water into two separate gaseous products—one at the anode, comprising essentially gaseous oxides of carbon, and the other at the cathode which is essentially pure hydrogen. We called this process electrochemical gasification of coal or, alternatively, coal-assisted water electrolysis. Coal contains a wide variety of organic molecules rich in carbon. Focusing only on the carbon of the coal the reactions of the electrochemical coal-gasification process, in simplified stoichiometry, would be:

Anode: $$\frac{X}{2}\mathrm{C(s)} + X\mathrm{H_2O(l)} \rightarrow \frac{X}{2}\mathrm{CO_2(g)} + 2X\mathrm{H^+} + 2X\mathrm{e^-} \quad (3)$$

Cathode: $$2X\mathrm{H^+} + 2X\mathrm{e^-} \rightarrow 2X\mathrm{H_2(g)} \quad (4)$$

The reversible thermodynamic potential, $E°$, of half-cell reaction (3) is only about 0.21 V. We have now extended electrochemical coal gasification to the electrowinning of metals by substituting the half-cell reaction (3) (which consumes coal) for the half-cell reaction (1) which usually takes place during conventional electrowinning of metals from aqueous solutions of

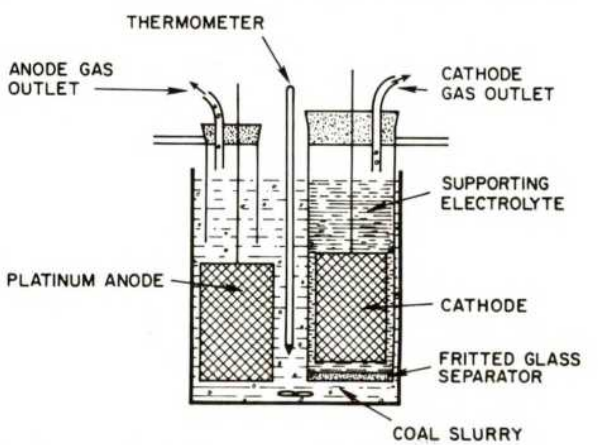

Fig. 1 Coal gasification cell: electrolyte volume, 80 cm^3; anode, 5.3 cm^2 (geometrical) platinum mesh, gauge 52; cathode, 8.4 cm^2 (geometrical) platinum mesh, gauge 52; stirring, magnetic, $\frac{7}{8}$-inch magnet).

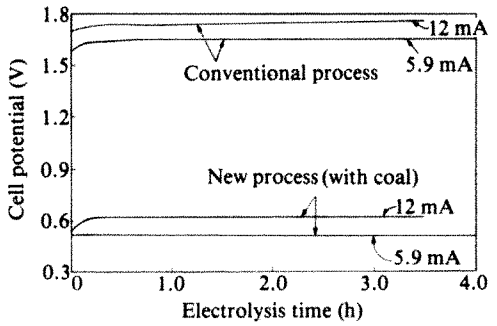

Fig. 2 Comparison of cell potentials of the copper electrowinning processes in galvanostatic conditions: Electrolyte, 0.125 M $CuSO_4$ and 0.5 M H_2SO_4; coal sample, N. Dakota lignite; slurry concentration, 0.15 g cm^{-3}; particle size, 74–88 μm; temperature, 60 °C.

their salts. By this coal-based innovation the total overall cell potential of the resulting metal electrowinning process is lowered by about 1.0 V with a corresponding significant reduction in the consumption of electrical energy. This new method of electrowinning from aqueous electrolytes is illustrated using preliminary experimental results for the coal-assisted copper electrowinning process.

Experiments were conducted in the simple cell shown in Fig. 1. The external e.m.f. was controlled by a potentiostat (PAR 371) and the electrodes (both anode and cathode) were Pt mesh, gauge 52 (0.004-inch diameter wire, Mathey Bishop Inc). Aqueous electrolytes were prepared with Baker analysed reagent grade sulphuric acid and Baker $CuSO_4 \cdot 5H_2O$ crystals. Coal slurries were prepared from pulverised North Dakota lignite coal; the ultimate analyses are described elsewhere[4]. Metal analysis was carried out on a Perkin-Elmer 460 atomic absorption spectrophotometer.

For comparison Cu was first deposited by conventional electrowinning without using coal. Accordingly, using the cell of Fig. 1, Cu was deposited on a platinum-mesh cathode from aqueous electrolyte (0.125 M $CuSO_4$ in 0.5 M H_2SO_4) at 60 °C, and at four different galvanostatic currents: 5.9, 7.95, 10 and 12 mA. The corresponding change in cell potential was recorded and typical cell potentials corresponding to the galvanostatic currents of 5.9 and 12 mA are plotted in Fig. 2. The conventional copper electrowinning reaction took place at corresponding cell potentials of about 1.65 and 1.73 V respectively. Figure 2 also shows the results obtained in parallel experiments, identical except that the coal was simultaneously oxidised at the anode according to equation (3) while Cu cations were reduced at the cathode according to equation (2). In these latter experiments, North Dakota lignite (NDL) coal slurry (0.15 g cm^{-3}) was introduced into the anode compartment of the cell and was anodically oxidised while copper deposited on the cathode in identical galvanostatic experimental conditions. As a result of the oxidation or gasification of the coal at the anode, the overall cell potential was lowered by ~1.1 V, compared to the conventional process. This is evident from Fig. 2. It is seen that the simultaneous anodic oxidation of coal lowers the potential by ~1.10 V, a value which is very close to the difference in half-cell potential between reaction (1) and (3).

Data on the current, electricity consumption and weight of Cu deposited are given in Table 1 for the conventional process, and in Table 2 for the new, coal-assisted process. Current efficiencies are also given computed from the ratio of the amount of Cu actually deposited to the equivalents of the charge passed during the experiment. The introduction of coal into the anode compartment during electrolysis evidently reduces current efficiency only slightly, at the worst about 2%. Comparing the right-hand columns of Tables 1 and 2 reveals that the simultaneous anodic oxidation of coal during Cu electrowinning reduces the electrical energy consumption by a factor of about two-thirds or more. Whereas the conventional process uses only electrical energy, our new process uses both electrical energy (E_2) and the chemical energy (E_3') of coal directly. For a reasonable comparison of the energy consumption of the two processes, the chemical energy of the coal consumed should be converted into equivalent electrical energy. By the stoichiometry of reaction (3), the mass of carbon consumed to produce 1 kg of copper is approximately:

$$\frac{12\ \text{kg C}}{\text{kg atom C}} \times \frac{1\ \text{kg atom C}}{2\ \text{kg atom Cu}} \times \frac{1}{63.54} \frac{\text{kg atom Cu}}{\text{kg Cu}} = 0.0944 \frac{\text{kg C}}{\text{kg Cu}}$$

Based on the enthalpy of combustion of carbon, this corresponds to a chemicothermal energy consumption of

$$E_3' = 0.0944 \frac{\text{kg C}}{\text{kg Cu}} \times \frac{94{,}052\ \text{kcal}}{12\ \text{kg C}} \times \frac{4180\ \text{J}}{\text{kcal}} \times \frac{1\ \text{kWs}}{10^3\ \text{J}} \times \frac{1\ \text{h}}{3{,}600\ \text{s}}$$

$$= 0.859 \frac{\text{kWh}}{\text{kg Cu}}$$

Assuming a practical efficiency of 35% for conversion of the combustion enthalpy of carbon (coal) into electrical energy, the electrical energy equivalent to the coal consumed is:

$$E_3 = (0.859)(0.35) = 0.300 \frac{\text{kWh}}{\text{kg Cu}}$$

Using these values of E_3' and E_3 with the values of E_1 and E_2 from Tables 1 and 2, the total energy requirements and also the net energy savings have been calculated for the new process and are reported in Table 3. Compared to the conventional process, the new coal-consuming process requires about 45% less net equivalent electrical energy for producing the same amount of copper.

A more telling comparison of these processes might be on the basis of relative energy costs based on assumed costs of US $0.02 per kWh for electricity and $35.00 per ton ($0.0514 per kg C) for coal assumed to be 75% carbon. Using mean values for E_1 and E_2 these costs are:

For the conventional process: Cost = ($0.02) · $\bar{E}_1$ = $0.031 per kg Cu.

For the new coal-assisted process: Cost = ($0.02) · $\bar{E}_2$ + (0.0944)($0.0514) = $0.0147 per kg Cu.

The savings in energy cost appears, therefore, to be ~50%.

In the experiments discussed so far, NDL coal which contains about 11.7% ash has been used as a reactant. The ash composition suggests the possibility of the presence of impurities such as Al, Fe, Ti, Ca, Mg, Na and K ions in the electrolytes. Consideration of the thermodynamic potential of the M–M^{x+} couple of these metals indicates that only iron might interfere with the copper deposition for which half-cell potentials have been reported[6] as follows:

$$Cu^{2+} + 2e^- = Cu \qquad E^\circ = 0.337\ \text{V}$$

$$Cu^{+} + e^- = Cu \qquad E^\circ = 0.521\ \text{V}$$

$$Cu^{2+} + e^- = Cu^{+} \qquad E^\circ = 0.153\ \text{V}$$

Table 2 Current efficiency and electrical energy consumption during copper deposition: new coal-assisted process

Reaction rate I (mA)	Total coulomb consumed It (C)	Theoretical Cu equivalent to the charge passed W_1 (g)	Measured amount of Cu deposited W_2 (g)	Current efficiency $(W_2/W_1) \times 100$ (%)	Electrical power consumed $E_2 = (I \int V\,dt)/W_2$ (kWh kg^{-1})
5.90	105.84	0.03485	0.031115	89.4	0.468
7.95	132.61	0.04366	0.04062	93.0	0.428
10.00	142.80	0.04702	0.04407	93.3	0.524
12.00	129.60	0.04267	0.04063	95.2	0.552

Electrolyte, 0.125 M $CuSO_4$ and 0.5 M H_2SO_4; Temperature, 60 °C; North Dakota lignite coal concentration 0.15 g cm^{-3}; particle size, 74–88 μm.

Table 3 Savings in energy consumption

Galvanostatic reaction rate I (mA)	Total energy consumption in the new process E_2+E_3 (kWh per kg Cu)	Net equivalent electrical energy consumed in this new process E_2+E_3 (kWh per kg Cu)	Net savings in equivalent electrical energy $E_1-E_2-E_3$ (kWh per kg Cu)	Net equivalent energy savings $\frac{(E_1-E_2-E_3)}{E_1}\times 100$ (%)
5.9	1.328	0.77	0.75	49.3
7.95	1.29	0.73	0.78	51.6
10.0	1.384	0.826	0.694	45.7
12.0	1.412	0.852	0.768	47.3

Reported[6] potentials of the different iron couples are:

$$Fe^{2+}+2e^-=Fe \qquad E^\circ=-0.440\ V$$
$$Fe^{3+}+e^-=Fe^{2+} \qquad E^\circ=0.771\ V$$
$$Fe^{3+}+3e^-=Fe \qquad E^\circ=-0.036\ V$$

The ash of NDL coal contains 12.5% Fe_2O_3 (other coals contain even less iron). Therefore iron is the only large-scale impurity which should be removed in a continuous process because reduction from the ferric to the ferrous state would reduce current efficiency for copper deposition and would increase the power consumption. Note that iron is generally also the only large-scale impurity present in copper ore itself and the technology for iron removal is well established, for example, by air oxidation of Fe^{2+} to Fe^{3+} which can easily be made to precipitate as the hydroxide. In some industrial processes ferric ion concentration is kept high to promote faster leaching of sulphide ores.

The purity of the electrodeposited copper was determined by dissolution in HNO_3 followed by atomic absorption spectrophotometry. In all experiments the purity of the deposited copper was >99%. The use of NDL or the presence of its ash in the electrolyte does not seem to have any significant effect on the copper purity. While our results, showing significant reduction in the energy requirement, pertain to one specific reaction system, similar observations are expected for other metal electrowinning reactions in aqueous electrolytes. Anode materials other than platinum have also been investigated. Graphite rods and graphite felt anode (Union Carbide Corp.) performed as well as platinum; copper plate cathodes have also been successfully tested.

Although, in an energy conscious environment this method looks promising, the practical applicability of the process depends on: (1) Achieving current densities sufficiently large to keep the capital cost economical; in our simple laboratory experiments no attempt has been made to increase current densities which were far lower than those used in industrial processes. (2) Almost total consumption of the carbon-value of the coal particles. (3) The influence of the particular coal and its ash content on electrowinning kinetics and on the properties and morphology of the deposited metal. (4) Preventing build-up in a continuous process of impurity cations which might compete with copper ions in electrolysis; such impurities would have to be removed continuously, for example by air oxidation of Fe^{2+} to precipitate ferric hydroxide.

Impact of CO_2 on cooling of snow and water surfaces

THE levels of CO_2 in the atmosphere are being increased by the burning of fossil fuels and reduction of biomass[1–3]. It has been calculated that the increase in CO_2 levels should lead to global warming because of increased absorption by the atmosphere of terrestrial longwave radiation in the far IR (>5 μm)[4–7]. From model computations, CO_2 is expected to produce the largest climatic effect in high latitudes by reducing the size of ice and snow fields[4]. We present here computations of spectral radiative transfer and scattering within a snow pack and water. The results suggest that CO_2 significantly reduces the shortwave energy absorbed by the surface of snow and water. The energy deficit, when not compensated by downward atmospheric radiation, may delay the recrystallisation of snow and dissipation of pack-ice and result in a cooling rather than a warming effect.

We consider here the spectral absorption of CO_2 in the near IR portion (wavelength $0.75 \simeq 5.0$ μm) of incoming shortwave radiation with respect to the role of near IR in the heating of the uppermost (active) layer of snow and of water. Calculations were made to determine the impact of doubled CO_2 on the amount of short wave radiation absorbed in these layers in conditions typical of the start and the end of the local snow and ice season[8–10]. At this stage, other components of the heat balance such as transfer of sensible and latent heat, longwave atmospheric radiation, heat convection, and so on, were not considered.

To study the solar heating of snow, analytic expressions for the flux and divergence of flux (heat flux) were obtained by solving the radiative transfer equation in the modified two-stream approximation[11]. The scattering and absorption within the snow-cover by the randomly distributed ice grains were represented by a single scattering albedo and anisotropic phase function. Geometric optics calculations[11,12] were used to relate the scattering and absorption parameters to the grain size and density. The spectral flux, $F\lambda(z)$, and the negative of the derivative of spectral flux, $F^1\lambda(z)$, at a depth z within the snowpack were obtained from the equations:

$$F_\lambda(z)=[I_+(z)-I_-(z)]f_\lambda W_0$$
$$F^1{}_\lambda(z)=\sqrt{2}\gamma_e(1-\omega)[I_+(z)+I_-(z)]f_\lambda W_0$$

where

$$I_+(z)=c_1\left[1+\frac{(1-\omega)\sqrt{3}}{a}\right]\exp(-a\tau)+c_2\left[1-\frac{(1-2)\sqrt{3}}{a}\right]\exp(a\tau)$$

$$I_-(z)=c_1\left[1-\frac{(1-\omega)\sqrt{3}}{a}\right]\exp(-a\tau)+c_2\left[1+\frac{(1-\omega)\sqrt{3}}{a}\right]\exp(a\tau)$$

$$c_1=\frac{1}{\left[1+\frac{\sqrt{3}(1-\omega)}{a}\right]\left[1+\frac{\alpha(\alpha-R)}{R\alpha-1}\exp(-2a\tau_0)\right]}$$

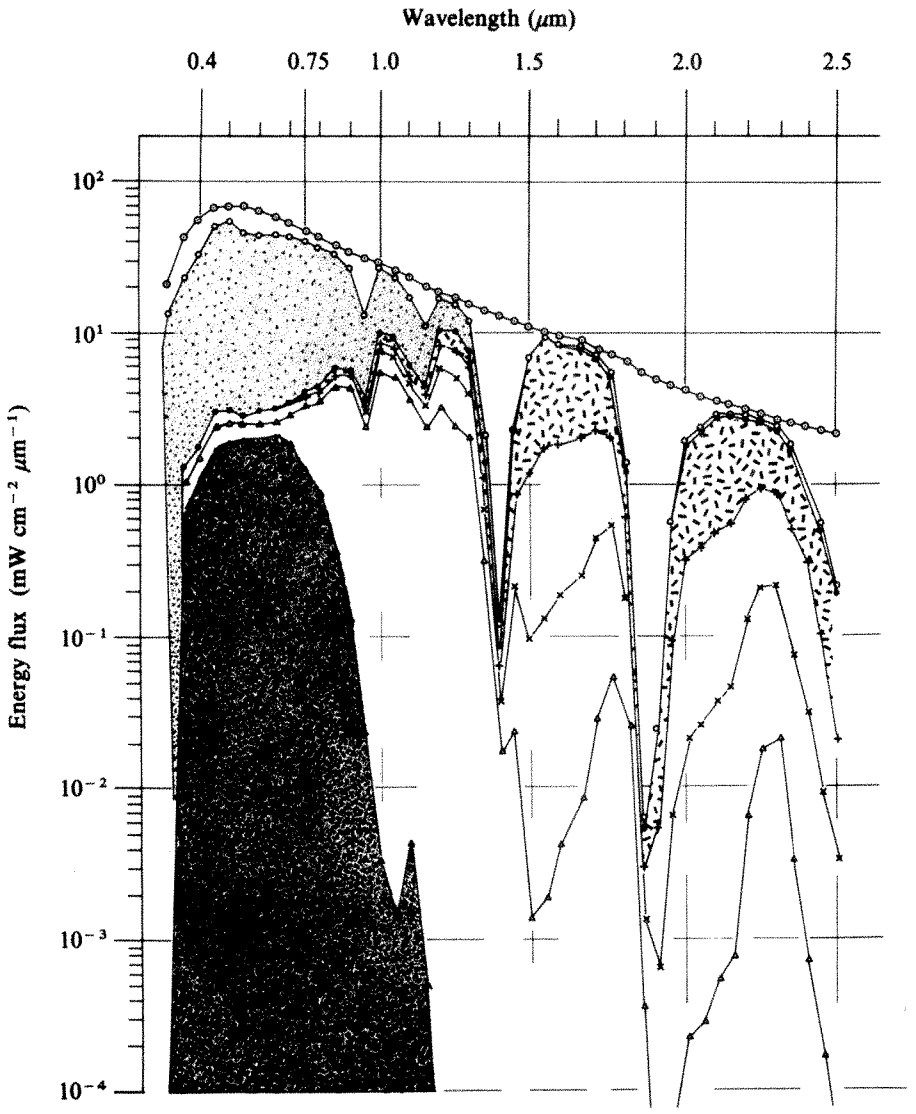

Fig. 1 Shortwave radiation flux in a snow pack in clear dry atmosphere at site A (see text), with 23° solar elevation and normal CO_2 level. Reflected radiation light stippled; energy absorbed in the uppermost 0.2 cm of a snowpack is marked with an intermediate tone; and energy penetrating into the underlying surface is heavy dark stippled. Almost all energy absorbed by snow is in the wavelength above 0.75 μm. ⊙ Top atmosphere; ○ surface; ● surface penetration; + 0.2 cm; × 0.5 cm; △ 1 cm; ⋀ 15 cm.

$$c_2 = \frac{\left(\frac{\alpha - R}{R\alpha - 1}\right)\exp(-2a\tau_0)}{\left[1+\frac{\sqrt{3}(1-\omega)}{a}\right]\left[1+\frac{\alpha(\alpha-R)}{R\alpha-1}\exp(-2a\tau_0)\right]}$$

where $I_+(z)$ is the intensity of downward oriented radiation; $I_-(z)$ the intensity of upward oriented radiation; f_λ the fraction of the solar flux incident on the snowpack within a narrow band centred around wavelength λ; W_0 the insolation to the top of the atmosphere; ν the radius of ice grains (cm); ρ the density of the snowpack (g cm^{-3}); h the thickness of the snowpack (cm); β the fraction of energy scattered in the backward hemisphere in single scattering (≃0.065); κ_λ the spectral absorption coefficient of ice (cm^{-1}); $C_{1,2}$ the integration constants; R the reflectance of the underlying snow surface (ice); $\tau = \gamma_e z$ the optical thickness; and $\tau_0 = \gamma_e h$ the total optical thickness of the pack.

Also

$$a = (3(1-\omega)(1-\omega+2\omega\beta))^{1/2}$$

$$\alpha = 1 - \frac{2(1-\omega)^{1/2}}{(1-\omega+2\omega\beta)^{1/2}+(1-\omega)^{1/2}} = \text{spectral reflectance}$$

$$\gamma_e = \left(\frac{3}{2\nu}\right)\frac{\rho}{0.917} = \text{extinction coefficient}$$

$$\omega = \tfrac{1}{2}+\tfrac{1}{2}\exp(-1.67\kappa_\lambda\nu) = \text{single scattering albedo}$$

In the absence of thermal conduction the rate of radiative heating was given by the equation:

$$H = \frac{1}{c\rho}\sum_\lambda F^1{}_\lambda(z)$$

where $c = 0.5$ is the specific heat of snow.

The values of the spectral reflectance, and the asymptotic flux extinction coefficient calculated from the model[13] are in good agreement with the observations[14]. We used the Delta–Edington approximation to calculate the radiative flux transfer and absorption in water[15]; the albedo was computed after Ivanoff[16]. Results agree with observations[17]. Atmospheric and radiative conditions approximately represent two sites. Site A is on land at latitude 43° N; water content in the atmospheric column is 0.9 g cm^{-2} and the Ångström turbidity factor 0.08. Noon solar elevation is 23°, as in the second half of December. Snow is underlain by soil. Site B is at latitude 78° N; atmospheric water content is 0.5 g cm^{-2} and the Ångström turbidity factor 0.02. Noon solar angle is 35°, as in early June when snow melt starts on top of the sea-ice.

In both cases the ozone path length is 0.35 cm, barometric pressure is 1,000 mbar, snow density is 0.22 g cm^{-3}, grain radius is 0.35 mm (that of moderately aged snow) and snow thickness is 15 and 30 cm. Normal concentration of CO_2 was conservatively taken as 315 p.p.m. although considerably higher winter values have been reported from the Northern Hemisphere in recent years[18]. Computations were performed for solar elevation changed in a daily cycle at hourly intervals. Flux was computed at a depth of 0, 0.2, 0.5, 1.0, 2.0, 5.0, 15.0 and 30.0 cm for snow

See text for atmospheric composition and snow properties.

and an additional 100 cm for water. In each case, parallel computation was done for a normal atmospheric content of CO_2, and then for the doubled level. The attenuation spectra of CO_2, water vapour, ozone and aerosols were taken from refs 19 and 20. CO_2 absorbs in the near IR bands 1.40–1.65 μm, 1.90–2.10 μm, and 2.80–2.90 μm.

Figure 1 shows the calculated spectral distribution of the shortwave radiation flux at different depth levels of the snowpack. The near IR is mostly absorbed in the upper 0.5 cm whereas the visible light is reflected or penetrates to the bottom of a pack. Similarly, in clear freshwater, the near IR is absorbed at the surface, whereas the visible radiation penetrates to deeper layers. Over 90% of the shortwave radiation absorbed in the uppermost 2 mm of snow and water is in the spectral range greater than 1 μm (Fig. 2).

Doubled CO_2 cuts the shortwave-generated heating rate at the snow surface on sites A and B by about 2% (1.7–2.6%, see Table 1) and that of the water surface on site A at noon by 4.4%. At a depth of 0.2 cm the difference is 1.0–1.6% in snow, but only 0.3% in water. The heat flux in snow and water layers below 1 cm is not affected.

Establishment of snow cover profoundly alters the radiative exchange taking place at the land surface because of the high visible albedo and high thermal emissivity of snow. Snow fields become areas of intensive radiative cooling where cold and dry polar atmospheric masses develop. A few days after a snowfall both the albedo and the surface emissivity of snow decreases. This is mainly due to the recrystallisation of snow in the active layer. The changes take place even in uninterrupted subfreezing weather[21–23]. The energy for snow metamorphism is provided largely from the absorbed near IR. As the shortwave transmissivity of ageing snow increases, the temperature at the base of the pack can rise to a sufficiently high level and initiate the bottom melt. Weaver *et al.*[24] described such internal melt of snow in subfreezing weather on top of the fast ice in the Western Davis Strait. Incipient meltwater puddles formed on the ice–snow interface. During 1971–73 the process began in early June and lasted 2–3 weeks, before the snow dissipated and open water pools formed.

It is logical to expect that the CO_2 related reduction of the near IR to the snow surface would delay the recrystallisation, maintain high albedo, and consequently delay the onset of subsurface melt.

Arctic sea-ice breaks under wind stress throughout the year, exposing leads of open water. In winter when the radiative input is low, and evaporative cooling strong, the water refreezes and the cracks are sealed. In spring and summer the exposed water does not refreeze, the ice floes disintegrate by wave action and are blown away into the open water where they melt. Thus the break-up starts when the absorbed radiation in the leads is sufficiently high to prevent refreezing. In clear cold weather, the

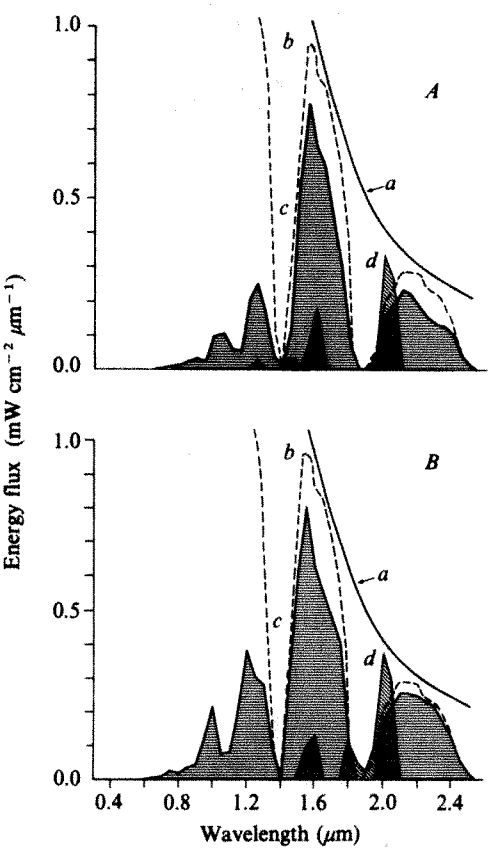

Fig. 2 Shortwave radiation absorbed in the uppermost 0.2 cm of snow (*A*) and clear fresh water (*B*) on site A at noon (see text). *a*, radiation at the top of the atmosphere; *b*, radiation reaching the surface; *c*, absorbed radiation; *d*, deficit due to CO_2 doubling, ×10.

increased CO_2 is likely to delay the onset of the break-up. It is also likely to facilitate an earlier freeze-up of shallow land based fresh water bodies. Apart from CO_2, some other trace gases such as NO_2 or NH_4, and the aerosols of volcanic or industrial origin also absorb in the critical bands and can have a similar effect.

We have to stress that several important radiative and micrometeorological processes were omitted in our model. For instance, the added heating of the atmosphere due to the presence of CO_2 was not calculated. The compensation cannot be complete in a dry subfreezing air of polar origin[27]. But in summer, when the air over the pack-ice in the central Arctic is relatively moist and thick clouds develop, less near IR reaches the ground, and CO_2 probably warms the system.

Obviously we are far from a comprehensive determination of the effect of CO_2 doubling on snow and ice fields. Our study demonstrates, nevertheless, that the final assessment of the CO_2 impact on global climate is too complicated to be reliably solved by simple annually-averaged general circulation models. Predictions of global warming derived from them should be considered highly tentative at best[27]. For reliable answers, improved models will have to be developed to handle in detail the different heating response of various surface types to changing spectral irradiance. Field observations will be needed to test the models.

The global impact of CO_2 increase remains uncertain, but it is possible that the related reduction of shortwave radiation absorbed in snow active layers and at the water surface may contribute to an extension of snow and ice seasons and to an intensified production of cold arctic air masses in winter, spring and autumn. Such a process would be marked by delayed snowmelt in spring, and early snow deposition in autumn, a development not inconsistent with the fluctuations of snow covers observed from satellites in the past 12 yr[25,26].

An apparent periodicity in an index of volcanic activity

A STOCHASTIC SIMULATION of Lamb's dust veil index[1,2] (DVI) is used here to show that statistically significant peaks in the variance spectrum of geophysical or climatic data are not necessarily evidence of regular, or even quasi-regular, oscillations. The DVI is an annual measure of the amount of volcanic dust in the stratosphere, based on a variety of information, for the period 1500 to the present. Kelly[3] has noted the significant correlation of the DVI with various aspects of climatic change in the North Atlantic–European sector on time scales of 50 yr and more, and has shown that the variance spectrum of the DVI contains a statistically significant peak at 7–8 yr. This peak is also present in the spectra of certain climatic and atmospheric circulation parameters. Kelly[3] has suggested that this apparent periodicity in stratospheric dust content is more likely to be due to the chance occurrence of volcanic eruptions at 7-8 yr intervals during the limited period of record, rather than to a forced, regular cycle in volcanic activity. We now propose an alternate explanation: that the formulation of the DVI produces the spectral peak.

In his formulation of the DVI, Lamb assumes that, unless there is evidence to the contrary, after an explosive volcanic eruption the dust remains in the stratosphere in sufficient quantities to affect the radiation received at the Earth's surface, and hence climate, for four years, and that the dust amount decays linearly over that time. This assessment is largely based on the observed radiation deficits following the major eruptions of the past 100 yr and on the limited number of direct observations of the stratospheric dust load made in recent decades. Most studies of stratospheric dust loading due to volcanic activity assume an exponential, not linear, decay of the original dust injection with a relaxation time of about one year[4]. The linear decay approximates the period of most rapid fall-off of the exponential decay, integrated in yearly steps. Our results are not, however, valid for the case of an exponential decay, and the applicability of the general statistical point made here to the question of associations between volcanic activity and climate will be discussed elsewhere. The characteristic signature of a single eruption, as it appears in the DVI, is a decaying ramp function. The DVI record has an irregularity spaced saw-toothed and at times cyclical appearance due to the superposition of many such events (Fig. 1*a*).

Our hypothesis is that this formulation alone will produce a peak in the variance spectrum of the DVI at about 8 yr: twice the length of the ramp function. A stochastic simulation technique was used to test this hypothesis. Two parameters were allowed

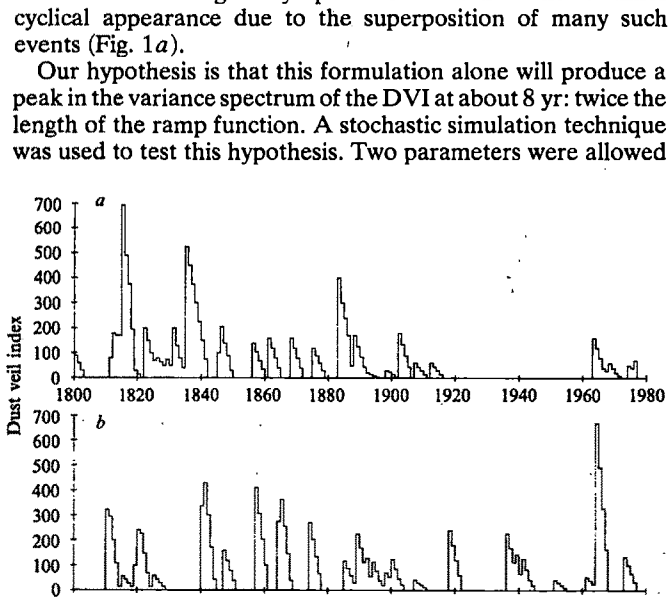

Fig. 1 *a*, Lamb's DVI: 1800–1976[1,2]. The isolated eruptions about 1860 show the ramp formulation clearly. *b*, Stochastic simulation of the DVI, with an eruption probability of 0.3 and ramp length of 4 yr.

© Macmillan Journals Ltd 1979

to vary in the stochastic simulations: the probability of an eruption within a particular year, and the ramp length. Simulated DVI records for a range of values of the two parameters were produced by a computer program using a random number generating routine. If the random number (in the range 0–1.0) assigned to a particular year was less than or equal to the eruption probability, an 'eruption' took place with a stratospheric dust injection given by a second exponentially-distributed random number. This distribution approximates to that of the actual DVI. The simulated dust-load was then linearly decayed over a period of years equal to the ramp length. A simulated DVI record is shown in Fig. 1*b*. In this case, the two variable parameters (the eruption probability and ramp length) have been set equal to those of the actual DVI. As it is a stochastic simulation the timing of the individual eruptions cannot be expected to be the same as in the actual DVI. In a series of experiments, the two parameters were varied through a realistic range of values. For each parameter pair, 1,000 records of length 117 yr were generated, the variance spectrum of each record was calculated, and a count was made of the number of peaks that were significant at the 5% level in each frequency band. The length of the simulated records used in the spectral analysis was 117 yr to facilitate comparison with the spectral analysis of the DVI given by Kelly[3]. The spectra were calculated using a fast Fourier algorithm, the spectral estimates were smoothed, and a white or red noise null continuum was assumed in a significance testing depending on whether or not the lag one autocorrelation coefficient departed significantly from zero.

Varying eruption probability over a wide range (0.1–0.9) produced little change in the resulting histograms (Fig. 2). This implies that a degree of superposition of the ramp functions does not obscure the spectral signal with a ramp of a few years' length. The following discussion is therefore restricted to the case of an eruption probability of 0.3 corresponding to that of the actual DVI. While this value is representative of the most reliable portion of the DVI record from 1800 to date, the eruption probability does in fact vary widely on the decadal and century-to-century time scale. The resulting histograms for ramp lengths of 4 and 6 yr are shown in Fig. 3. Clearly, as hypothesised, a spectral peak occurs at a period twice the length of the ramp function. Note that the odd harmonics of twice the length of the ramp function also appear in the histograms. As a control, we show the histogram resulting from an analysis of a set of simulations with zero ramp length (Fig. 3*c*). In this case, the total dust load was assigned to the year of the eruption and none to subsequent years. The histogram is smooth, as would be expected from a large sample of white noise spectra. This confirms that it is the ramp function alone which gives rise to the spectral signals seen in Figs 3*a* and 3*b*.

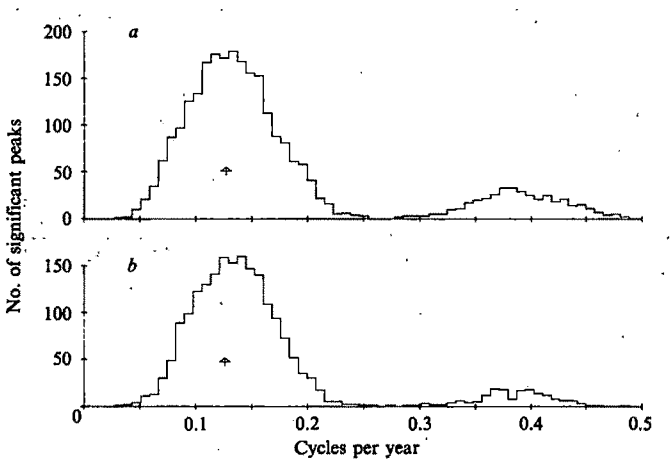

Fig. 2 Count of number of significant peaks per frequency band in the spectra of 1,000 simulations with ramp length of 4 yr and eruption probabilities of: *a*, 0·9; *b*, 0.1. Arrows indicate hypothesised location of spectral peaks.

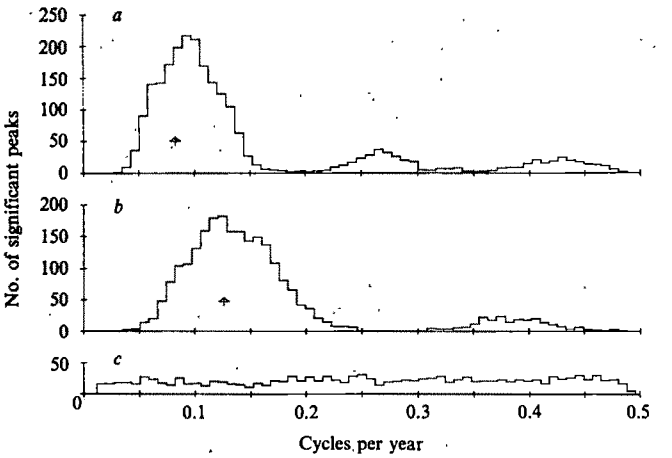

Fig. 3 Count of number of significant peaks per frequency band in the spectra of 1,000 simulations with an eruption probability of 0.3 and ramp lengths of: *a*, 6 yr; *b*, 4 yr; *c*, 0 yr. Arrows indicate hypothesised location of spectral peaks.

Two conclusions can be drawn from this analysis. First, the 7–8 yr peak in the variance spectrum of the DVI is not necessarily evidence of a regular, predictable cycle in volcanic activity. It arises from the formulation of the DVI and indicates the existence of ramp functions of length 4 yr in the data. A 7–8 yr cycle will not necessarily appear in the DVI when filtered, as the DVI is a summation of such ramp functions with random phase. This does not, however, detract from the value of the 7–8 yr spectral peak as a statistical characteristic of the DVI. It is the interpretation of this signal that is under discussion, not its reality, and it can be validly used for comparison with climatic data. The question of whether or not the linear decay is a realistic approximation to the fall-out of stratospheric dust and/or the climatic response to volcanic dust-veils, does, however, warrant further investigation. Second, we note that if there is a mechanism within the climate system which has the decay characteristics of a ramp function, for example, ocean–atmosphere interaction, then this could give rise to a spectral peak which may be misinterpreted as evidence of a regular climatic cycle.

We thank Ms B. M. Gray, Dr T. M. L. Wigley and Dr G. J. Janacek for helpful discussions, and Dr D. H. Tarling for his suggestion which prompted this analysis. This research was supported by the Office of Naval Research, grant N00014-77-G-0074.

The Tweeddale Granite—a newly discovered batholith in the Southern Uplands

ABOUT 2,500 gravity stations have been established in South-east Scotland by members of the Department of Geophysics, University of Edinburgh (Fig. 1). We report here a negative long-wavelength gravity anomaly over the Southern Uplands, running SW to NE parallel to the Caledonian trend. The gravity anomaly is interpreted as being due to an underlying granite

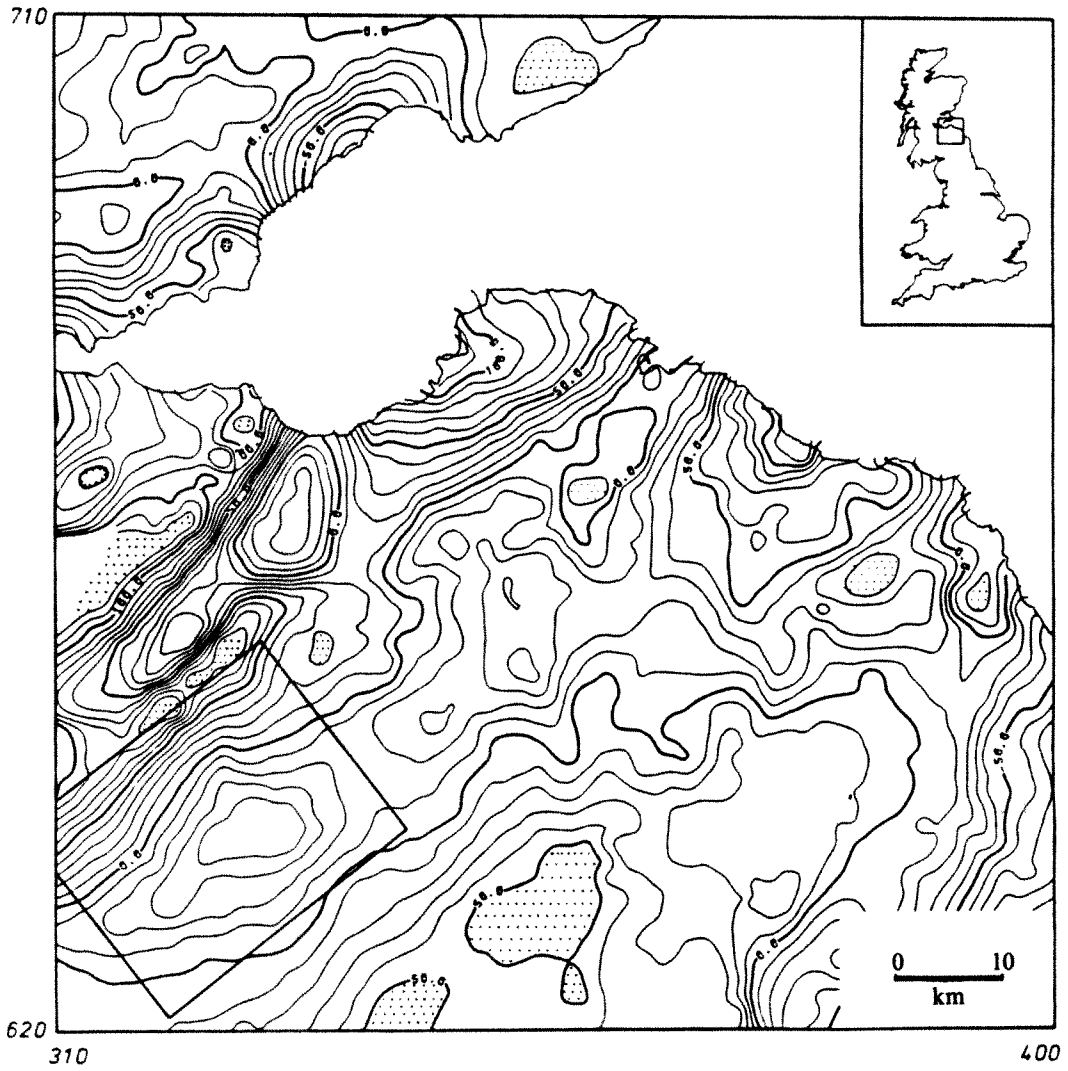

Fig. 1 Bouguer anomaly map of SE Scotland, outlining the area covered by Fig. 2, the residual anomaly map. Gravity data on both figures are referred to ISGN(1971)–GRS(1967). Contour interval 10 gu (= 1 mgal = 10^{-5} m s^{-2}, Stippled closures are high.

batholith, modelled in detail in the district of Tweeddale, where our station density averages 0.5 km^{-2}. Elsewhere in the Southern Uplands, the average coverage is 0.3 km^{-2}.

In Tweeddale the surface geological exposure to the south-east of the Southern Uplands Fault is relatively uniform. The SW–NE trending belt of Ordovician shales and graywackes is followed to the south by similar Silurian sediments as far as the Northumberland–Solway basin. Within the Lower Palaeozoic there are occasional small lenses of black shale, sometimes in the Northern Belt with radiolarian chert and pillow lavas. The whole sequence is interpreted as slices of oceanic sediment emplaced against a continental margin during the closure of the Iapetus Ocean[1]. Most of the small igneous features occur as felsite and porphyrite veins, with some relatively larger exposures, notably the porphyrites at Priesthope Hill (NT3540) and at Juniper Craigs (NT2536). Although most are now only evident as boulders in the drift, some small exposures of granite have been reported[2] and are shown on the Geological Survey map.

Because of the uniformity of the surface geology, the regional Bouguer anomaly field was estimated directly from the LISPB model[3,4], using the Nafe–Drake curve[5] to translate seismic velocity into density. The LISPB model was assumed to be two-dimensional, striking parallel to the Caledonian trend. The resulting residual Bouguer anomaly map is shown in Fig. 2, superimposed on a geological sketch map.

Our laboratory measurements on hand samples of Lower Palaeozoic sediments from many localities in the Southern Uplands fail to show sufficient systematic variation in density to cause the gravity low. Moreover, a two-dimensional extension of Nettleston's method[6], fitting a second degree surface separately to each 10 km National Grid square, also gave only a small density variation: over nine squares, the computed Bouguer density was $2{,}711 \pm 26$ kg m^{-3}, compared with an average from hand specimens of $2{,}708 \pm 21$ kg m^{-3}. The latter was calculated from 46 samples collected from eight locations. If we attempt to model the gravity low by a variation in sediment thickness, quite excessive values (>20 km) are required underlying the centre of the negative anomaly for any reasonable basement density; but it is here that the shortest wavelength features of the anomaly field occur, rather than at the margins. Evidence supporting a granite batholith is discussed below.

The centre of the main gravity low in Fig. 2 is near the outcrop of the numerous minor acid intrusives mapped in the Tweeddale area by the Geological Survey. This, in itself, suggests that the granites may be part of a more significant structure than is indicated in the field. To the SW along the Caledonian trend there are major granite exposures in South-west Scotland and Ireland, where detailed studies have already been carried out[7–11]. Recent regional interpretation of Bouguer anomalies in South-west Scotland[11] suggests that the granite plutons are connected at depth as a single massive batholith extending along the Caledonian trend. The existence of a granite batholith, both in South-west Scotland and along strike in South-east Scotland, is consistent with plate tectonic models for the evolution of the British Caledonides[12,13]. The Tweeddale area has been persistently elevated, at least since Upper Silurian times when it formed part of an emergent land mass called Cockburnland[1,14]. The anticipated mineralisation is only sporadic in the Southern Uplands and is not strongly developed in Tweeddale: historically, lead ore was worked at a few localities near the Tweed Valley[15,16], most extensively at the abandoned Grieston Mine (NT3136) but also at Dalwick (NT1734) and Dumbetha

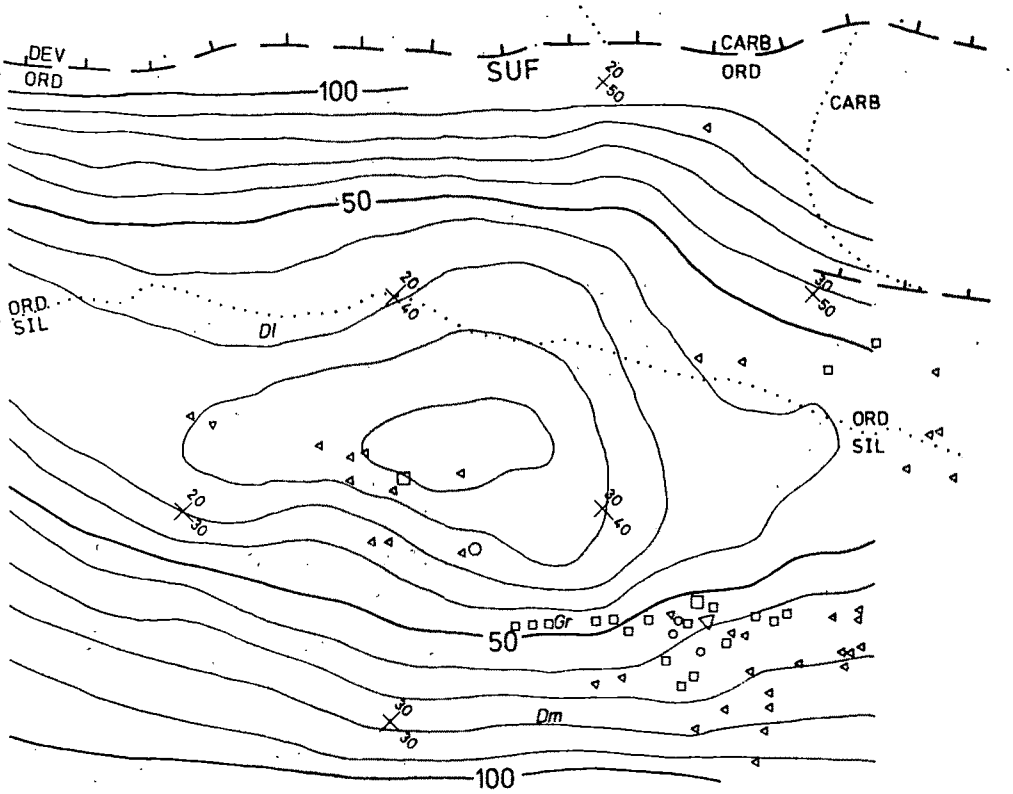

Fig. 2 Residual Bouguer anomaly map of the Tweeddale area, superimposed on a geological sketch map. Contour interval 10 gu. Intersections show the corners of 10 km National Grid squares. (NT3433). Geochemical analyses of organic material in the Moffat Shales[17] do indicate sharply increased thermal alteration towards the north, where we model the granite intrusion.

Residual gravity anomalies, interpolated onto a regular grid, were inverted by a three-dimensional modelling program, which adjusts the topography on a single interface of contrasting density. A unique model inversion exists if the density contrast and the depth to the interface at one point are known and the depth is single-valued everywhere.

A density contrast of $-70\ kg\ m^{-3}$ between Ordovician and Silurian sediments and the granitic rock was assigned (2,720–2,650 $kg\ m^{-3}$). Published densities of exposed granitic rocks in South-east Scotland[2] vary between 2,630 and 2,800 $kg\ m^{-3}$ and do little to constrain the interpretation. From a few massive boulders on Kailzie Hill (NT2836) and Kernie Law (NT3439), we found a saturated density of 2,628 (2,644) ± 9 $kg\ m^{-3}$ (11 samples), with 2,663 (2,674) ± 27 $kg\ m^{-3}$ (42 samples) for nearby porphyrites and felsites (grain densities in brackets). In South-west Scotland, the Fleet granite has been modelled[10] with a density of 2,630 $kg\ m^{-3}$, while the Griffel granodirite was interpreted[8] with a gradational density between 2,640 and 2,710 $kg\ m^{-3}$.

The depth-scale is more uncertain: a three-point depth rule[18] suggested that the interface is less than 2.6 km deep near the centre of the anomaly, while the maximum amplitude/maximum gradient ratio put the centre of mass at < 6.5 km. Figure 3 shows a typical three dimensional model inversion, here with a central point fixed at 2 km depth. The shape is typical for a batholith with outward sloping sides extending to a depth of 10–12 km and three small bosses coming near to the surface close to the porphyrite outcrops. This model is consistent with the barycentre estimate as well as seismic and magnetotelluric models showing a boundary at about 12 km depth.

Ingham (personal communication) finds a highly resistive layer ($10^4\ \Omega m$) overlying a good conductor ($10^2\ \Omega m$) at a depth of 10–12 km, from a one-dimensional inversion of magnetotelluric data from sites at Earlyburn (NT2249), Peebles (NT2740), Yarrow (NT2924) and Borthwick Brae (NT3616). The high overlying resistivity ($10^4\ \Omega m$) is indicative of a low-porosity igneous or metamorphic rock and so is also consistent with our granite hypothesis. Jacob[19] interpreted seismic arrivals at the Eskdalemuir array in terms of a 6.44 $km\ s^{-1}$ refractor at a depth of 12 km, a model which is not inconsistent with the later LISPB result[3], where this mid-crustal refractor was only poorly constrained. Although the LISPB profile actually crosses the Tweeddale area, it should not be expected to show the lateral

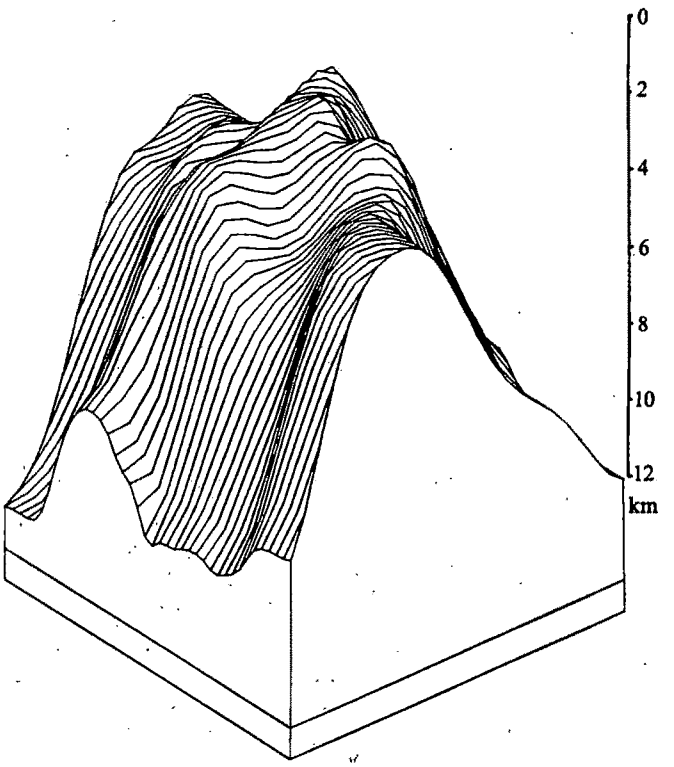

Fig. 3 Three-dimensional model of the upper surface of the Tweeddale Granite, viewed from the west and covering the same area as the residual anomaly map in Fig. 2. The computation includes infinite horizontal extensions from all edges of the model, the beginnings of which in the SW–NE direction are included in the drawing.

extent of the granite batholith: the 5.84 ± 0.02 km s^{-1} velocity observed for the supposedly Lower Palaeozoic sediments does not contrast with values found generally for granites[20,21], although the S-wave arrivals do give an unusually low Poisson's ratio[22], consistent with quartz enrichment.

Figure 1 suggests that the negative gravity anomaly, and therefore the granite batholith, extends northeastwards from the Tweeddale area towards the Berwickshire coast, although the pattern is confused by the Devonian sedimentary basins in Lauderdale and near Oldhamstocks (NT7471) and Eyemouth (NT9464). From the aeromagnetic map[23], and more clearly from filtered versions of it[24,25], there is reasonable long-wavelength continuity of a weak magnetic high, flanked to the north by a corresponding low, from the Criffel-Fleet-Doon plutons in SW Scotland to the Tweeddale area and thence northeastwards towards the coast. The 'granites' of Berwickshire and E. Lothian[2,26] show close petrological affinities to those in South-west Scotland. Only the Priestlaw (NT6562) and Lammerlaw (NT5163) exposures show localised, stocklike, positive magnetic anomalies, although all appear to be related to the same weak regional magnetic high traceable along the whole NE–SW length of the Southern Uplands. It seems reasonable to postulate that the whole Southern Uplands are underlain by the batholith, which is responsible for their longstanding and continued relatively high elevation and stability.

Lichenometry and earthquake age determination in central Asia

THE age of rock surfaces can be determined from the size of lichens growing on them[1]. We present here measurements of the species *Lecidea lactea* growing on rocks from the avalanches which occurred after the 1907 (Karatag) and the 1949 (Khait) earthquakes in Tadjikistan, Middle Asia. We show that their forerunning strong earthquakes occurred more than 100–130 yr previously.

The method of using lichens to date rocks is based on two assumptions: first, that the yearly rate of lichen growth is constant (on average within a given area), and second, that lichens settle on a newly exposed rock surface during the first year of exposure. We used lichens of species *Lecidea lactea* Ach. growing approximately in circles, which are convenient shapes for measurements. Each sample included, wherever possible, 100 measurements of the lichen diameter on compact groups of homogeneous rock surfaces.

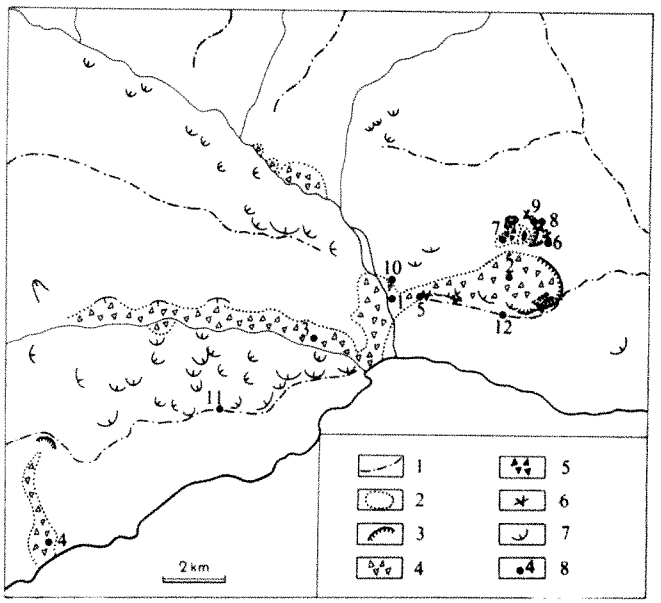

Fig. 1 Scheme of seismic dislocations and sites of lichenometric measurements in the epicentral area of the 1949 Khait earthquake. 1, Watersheds; 2, contours of landslides; 3, fracture walls of rock landslides; 4, landslides of 1949; 5, ancient landslides; 6, seismoravines in basement rock; 7, earth avalanches and slips of (mainly loess) rock; 8, sites of lichenometric measurements.

The investigation was in two stages: (1) the average growth rate of lichens on geologic objects of known age was determined, and (2) the age of undated objects was determined from measurements of the lichen diameter using the average growth rate values obtained.

The area of the 1949 Khait earthquake lies on the right bank of the Surkhob river in the outskirts of the village of Khait. The earthquake ($M = 7.4 \pm 0.1$) had caused a large landslide and an avalanche (length 10 km, height above 50 m) of mud and stone, as well as producing seismic ravines in hard rock[2–4]. To determine the average growth rate of lichens in this area, its dependence on exposure conditions and altitude (the ecology conditions) had to be estimated first. Two series of measurements were taken of boulders and debris in the upper and lower portions of a landslide[2,3] in the epicentral area of the 1949 Khait earthquake. The diameter distribution curves of lichens inhabiting the southern and northern surfaces of the boulders and debris were practically identical. Thus, the rate of growth can be taken to be independent of exposure conditions, but is highly dependent on altitude (Table 1) and this should be included in the calculations.

Table 1 shows that a number of statistical parameters of the rate of growth have been used: the arithmetic mean of diameter values (X_{mean}), the diameter of the most frequently occurring

Table 1 Basic statistical characteristics of average yearly growth (in mm) of lichens of species *Lecidea lactea*

Statistical characteristics of growth from diameter measurements	Khait area (mm yr^{-1}) Site 1 Altitude (m) 1,600	Khait area (mm yr^{-1}) Site 2 Altitude (m) 2,000	Karatag area (mm yr^{-1}) Site 1 Altitude (m) 1,700

The average age has been calculated for a reference height of 1,700 m.

objects (X^x), the mean diameter of the largest objects (X^x_{max}), the maximum diameter (X_{max}). We have also estimated the variance (mean squared deviation) (σ). We believe that such an approach greatly improves the accuracy attainable using the maximum diameter measurements alone[1,5] and confirms the desirability of combining several characteristics of growth rate[6].

Before lichenometry could be applied to objects of unknown age, they had to be classified into several groups according to outward appearance and geomorphologic criteria: (1) boulders in landslides probably dating from the 1949 earthquake (from indirect indications see refs 2, 3, and outward appearance); (2) walls in ravines that were either produced or renewed by the earthquake (our unpublished data); (3) ancient ravines and a landslide that were probably produced by a large earthquake

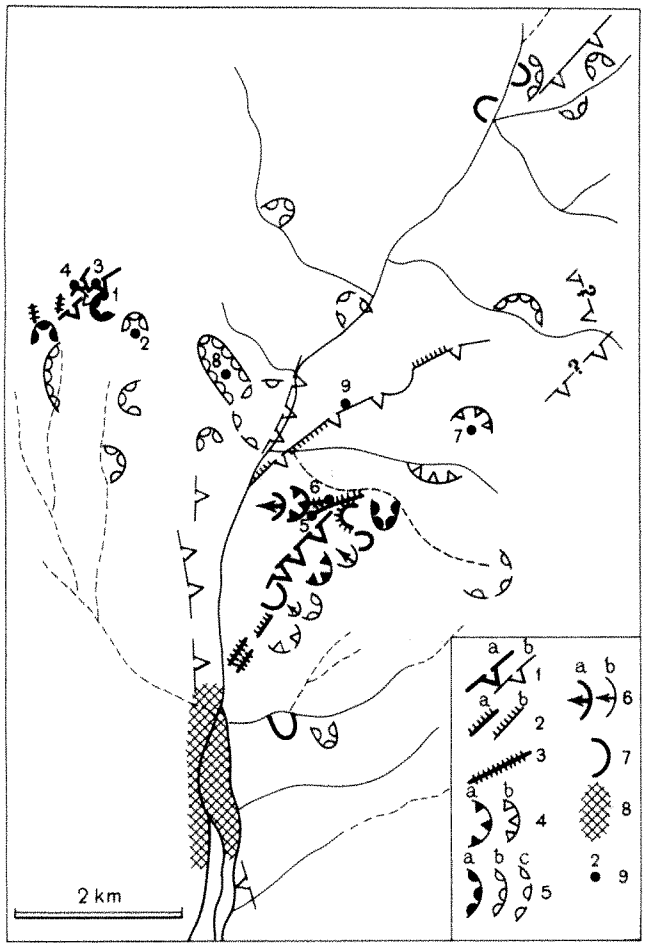

Fig. 2 Scheme of seismic dislocations and sites of lichenometric measurements in the epicentral zone of the 1907 Karatag earthquake. 1, Seismoravines; 2, terraces, escarpements; 3, cracks in loose sediments; 4, fracture walls of rock landslides; 5, landslides; 6, earthavalanches and slips of loose rock; 8, village; 9, sites of lichenometric measurement. Age by geomophologic criteria: a, fresh; b, somewhat earlier (late Holocene); c, ancient (pre-Holocene).

before 1949 (our unpublished data); (4) hard rock surfaces that are certainly older than the 1949 or any previous earthquake, or which were renewed during it.

Two or three objects from each group have been measured. Table 2 shows that recent landslides in the Yagman river valley and a part of the Surkhob valley around the village of Mirtob were actually formed during the 1949 earthquake; the latitudinal ravines in the watershed to the east of Khait were indeed formed during the 1949 earthquake, whereas the meridional ravines are much older, and were only renewed in 1949; the ancient landslide and ravines in the upper Daraihaus river are approximately of the same age, so that they can be considered as paragenetic formations of an earlier large seismic event (or several consecutive events); the earthquake-generated surfaces are younger than the other hard rock surfaces, that is the age of the early seismic dislocations in our study is not limited by the extreme size of lichens in the present conditions.

Thus, we may conclude that the epicentral area of the 1949 Khait earthquake had been struck by a similar sized earthquake a long time previously.

The 1907 Karatag earthquake area ($M = 7.4 \pm 0.1$) faces the southern foot of the Hissar range 50 km west of the town of Dushanbe. The objects studied by lichenometry in the epicentral area of the Karatag earthquake can also be classified into a number of groups: in addition to the wall of a joint that certainly results from the Chuyanchi earthquake of 21 October 1907 (ref. 7), and which is used here to determine the average growth rate of lichens in this part of the area (see Table 1), there are the following: (1) ravine walls and landslide boulders which we tentatively ascribe from their positions and outward appearance to the 21 October 1907 earthquake; (2) boulders in the landslide and walls in the ravine, supposedly a result of the 8 October 1907 earthquake; (3) boulders in ancient landslides and the walls of an ancient ravine, here associated with an earthquake(s) before 1907.

The results of lichenometric measurements in the Karatag area support the idea[8] that the landslide and ravines near the village of Chuyanchi (group (1)) are associated with the Chuyanchi earthquake of 21 October 1907. The landslides and ravines on the left bank (group (2)), which we had supposed to originate from the Karatag earthquake of 8 October 1907 have turned out to be much younger (29 ± 3 yr and 27 ± 7 yr from the age of the lichens. We consider, however, that this age only reflects a renewal of the surface rather than formation of the objects themselves.

The group (3) formations ascribed to an earlier earthquake some hundreds of years before 1907 (refs 8, 9), have an age of 200 yr according to lichenometry. A landslide on the left bank first investigated here (measurement site 7 in Table 3) can be tentatively associated with the large 1863 earthquake west of the Hissar range from some age determinations from the lichens on the boulders (123 ± 43 yr).

The two largest earthquakes that we know to have occurred in the Hissar–Kokshaal fault zone in Tajikistan cannot be considered to be random events as regards their place and time of occurrence. The investigation area has been struck with large ($6 < M \leq 7.5$) earthquakes during the past few hundred years with an interval of recurrence of at least 100–130 yr, but more likely 200–250 or more years.

Do circadian oscillators ever stop in constant light?

A TWO-DIMENSIONAL limit cycle model (Fig. 1) predicts the behaviour in darkness of both the *Drosophila pseudoobscura* circadian eclosion rhythm[1,2] and the mosquito *Culex pipiens quinquefasciatus* Say (*C. p. fatigans* Wied.) flight activity rhythm[3,4]. This model has been extended to explain features of rhythms in very dim light, but in constant 'bright' light it has been suggested that the dynamics are fundamentally different, with the system having a globally stable equilibrium point and hence no stable oscillation[1]. We propose here a simplifying modification: for each light intensity the dynamics are topologically equivalent, and thus for each there is a limit cycle, its position and amplitude being continuous functions of intensity. This interpretation avoids the awkward discontinuity between 'light' and 'dark' dynamics and emphasises the possibility of time-keeping at all light intensities. Furthermore, it provides a simple explanation for novel features of the *Culex* rhythm described here and previously[3], and allows us to treat some

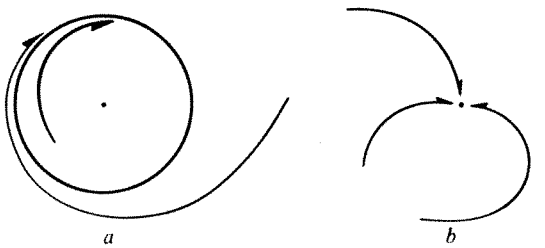

Fig. 1 *a*, Outline of the two-dimensional limit cycle model. The two variables are left unspecified, the oscillator is merely assumed to be attracted in darkness to a closed cycle, here represented by the bold circle. This cycle, the limit cycle, is assumed to be stable. If the oscillator is displaced from the cycle (typically by exposure to light), it will return as indicated by the two sample trajectories. There must be at least one point, the critical point, within the region bounded by the cycle, from which this return is indeterminate. *b*, A globally stable equilibrium point. All trajectories are attracted to a single point and thus such a system will always eventually reach a fixed non-oscillatory state.

important differences between *Culex* and *Drosophila* as merely quantitative. Finally, it suggests a new general strategy for the analysis of circadian rhythms and allows extensions of established theory that explain previously paradoxical results obtained for the two species (E.L.P. in preparation).

Both the *Drosophila* and *Culex* rhythms persist in continuous darkness, following, according to most models, a limit cycle in the two-dimensional state space. Phase is assigned to all limit cycle states relative to an arbitrary reference point. States out of the cycle can only be defined operationally: for example, that state realised after a phase 0 population is given a 1 s, 1 lx perturbation. However, states can be compared with the following protocol: transfer samples to darkness and let the original states be equivalent if the settled rhythms in darkness are in phase. The state space is thereby partitioned into equivalence classes or isochrons[2] (Fig. 2). Each isochron must include a unique limit cycle state and is labelled accordingly (isochron θ contains the state with phase θ). In practice, a state's isochron is determined by an assay experiment entailing transfer to darkness and comparison with a sample having known phase. In fact, not quite all states belong to an isochron, from some the return of the rhythm is unpredictable or not apparent. Such states comprise the phaseless set, which must include at least one point in the region bounded by the limit cycle.

The simplest possible topology is illustrated by

$$\dot{x} = y + \varepsilon x(a^2 - x^2 - y^2)$$
$$\dot{y} = -x + \varepsilon y(a^2 - x^2 - y^2) \qquad (1)$$

which has a limit cycle of radius a, centred on the phaseless critical point at the origin and straight, equally spaced radial isochrons. Each trajectory moves with constant angular velocity about the origin, independently of a and ε.

Our working hypothesis is that in darkness the circadian dynamical system has qualitatively the same form as equation (1). Note that in such cases, the isochrons divide state space much as longitudinal lines divide the Northern Hemisphere (Fig. 2), both systems yield incomplete yet useful information about location. The release–assay experiment uses this information to map a trajectory's route through state space: a population is synchronised at a chosen state, the release point, then released to free-run in constant test conditions—light of fixed intensity. The population follows the trajectory dictated by the dynamics at that light intensity. By periodically removing an aliquot and assaying the phase in constant darkness, the population's progress across the isochron map can be monitored. A plot of isochron against time gives an assay curve.

While this formal presentation and interpretation of release–assay experiments is new, the experimental design is not. Pittendrigh's *Drosophila* experiment[5] is one archetype (Fig. 2*a*). The dynamics in bright light apparently force trajectories to a point on one isochron, which, for this reason, we have defined to be isochron 0.

With these two concepts—a limit cycle in darkness and a globally stable equilibrium point in light—one can explain most light pulse phase resetting phenomena in *Drosophila*[2] and *Culex*. Yet, because the trajectory patterns in the two cases are topologically different (one with a limit cycle, one without), somewhere on the continuum of light intensity a change of form must occur. We prefer to eliminate the discontinuity, proposing instead that the trajectory patterns for all light intensities are topologically equivalent and, in particular, that a limit cycle always exists. For example,

$$\dot{x} = (y - b) + \varepsilon x(a^2 - x^2 - (y - b)^2)$$
$$\dot{y} = -x + \varepsilon(y - b)(a^2 - x^2 - (y - b)^2) \qquad (2)$$

where $a = \exp(-kI)$ and $b = y_\infty(1 - \exp(-kI))$ is a family of systems parametrically defined by light intensity, I. Each member of equation (2) is just a coordinate shift of a corresponding member of equation (1). Hence for each light intensity there is a limit cycle, radius a, centred on a single critical point $(0, b)$, the angular velocity of every trajectory around the critical point for that intensity is constant. As intensity tends to infinity, the corresponding system tends

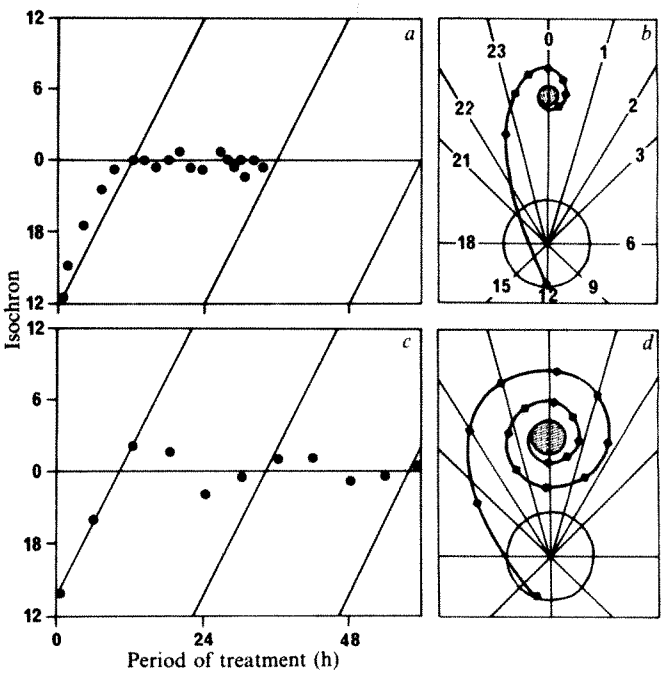

Fig. 2 *a*, *c*, Assay curves. The set of diagonals comprise the assay curve which would necessarily be obtained if the treatment condition were darkness and correspond to a population continuously following the dark limit cycle. *b*, *d*, Corresponding route maps. The route map is an interpretation of the associated assay curve. Each includes the dark limit cycle (unshaded circle), radial isochrons and the limit cycle assumed to exist in the given test conditions (shaded circle). Superimposed is the trajectory of the sample, inferred from the assay curve, assuming the dynamics are approximately those of equation (2). The predicted position of the sample every 3 h is indicated on the trajectory. *a*, *Drosophila pseudoobscura* assay curve. Data are redrawn from Fig. 7 of ref. 5. The release point was 'light on' in LD 12 : 12 (12 h light, 12 h dark), the test condition was 1,080 lx. Isochron 0 to which the assay curve seems to tend corresponds to Pittendrigh's ct: 12. *b*, *Drosophila pseudoobscura* route map. The proposed limit cycle is so small that any oscillation would be masked by the large experimental uncertainty. *c*, *Culex pipiens quinquefasciatus* assay curve redrawn from Fig. 2 of ref. 3. The release point was 'light on' in LD 12 : 12, the test condition was 50 lx. Each point is a mean of 24 mosquitoes with s.e. < 15 min. (The error bars in ref. 3 Fig. 2 are standard deviations.) *d*, *Culex pipiens quinquefasciatus* route map. The assay curve moves rather more quickly to its first maximum (12 h) than predicted, assuming constant angular motion around the 50 lx critical point.

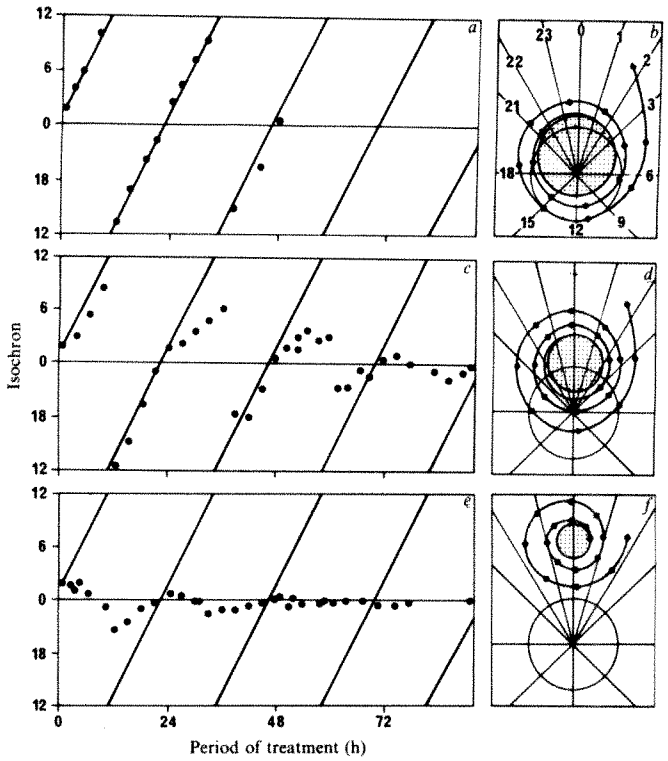

Fig. 3 The general organisation is as in Fig. 2. 'Light off' in LD 12:12 (180 lx) was chosen as the release point. (We have noted no difference between 50 and 180 lx.) Activity was monitored acoustically[4] and each point is the mean for 24 mosquitoes. *a*, *b*, 0.05 lx. The population follows the dark assay curve for the period examined. We infer that the 0.05 lx limit cycle is rather close in amplitude and position to the dark limit cycle. *c*, *d*, 0.5 lx. During the first 24 h the assay curve is near the dark assay curve. Correspondingly, the first cycle of the route map trajectory curls around the singularity cutting all isochrons. Over the second 24 h the assay curve jumps from isochron 6 to isochron 18, a result predicted if the trajectory cuts across the singularity at this time. Subsequent turns of spiral exclude the singularity, thereby failing to cut most isochrons. This is reflected by the reduced excursion of the assay curve in later cycles. *e*, *f*, 8 lx. The data points of Fig. 2*c* fall almost perfectly on those of *e* (after a 12-h time shift) indicating that the dynamic systems corresponding to 8 and 50 lx probably differ very little. The limit cycle, if it exists at this intensity, is too small to detect above experimental error, although the transient spiral is readily apparent.

smoothly toward the limiting case—the system with a stable focus at $(0, y_\infty)$.

This scheme is compatible with the *Drosophila* result, assuming that the amplitude of the limit cycle is sufficiently reduced for the oscillation to be experimentally irresolvable (Fig. 2*b*). However, it was the comparable experiment for *Culex*[3] (Fig. 2*c*) which yielded tangible evidence for the model. A spiral trajectory asymptotically approaching a limit cycle (Fig. 2*d*) is the only plausible explanation for the form of the assay curve, and the persistence of a circadian activity rhythm in the test conditions[3].

We propose that the organisation of these two dipteran circadian systems is qualitatively similar, discrepancies reflecting differences in treatment intensity and light sensitivity in the two cases. In support of this, note that a circadian eclosion rhythm continues in *Drosophila* in very dim light (0.05 lx white light[6] or 0.01 erg cm^{-2} blue light[2]), although an assay curve or its equivalent has never been presented.

The set of dim light assay curves for *Culex* suggests the smooth transitional sequence between darkness and light demanded by the model (Fig. 3). The curve for 0.5 lx (Fig. 3*c*) is of critical significance. There is, between 36 and 39 h, a phase jump of about 12 h, a feature compatible with the model only if the trajectory passes near the singularity of the isochron map during that time. Winfree[2] reports that for *Drosophila* the region around the singularity is a phaseless zone from which a return to rhythmicity is not observed in the dark. Results suggesting a similar phenomenon for *Culex* were seen in the 36 and 39 h assays. Depressed arrhythmic activity was recorded in these two samples, assumed to be lingering near the singularity. Although to some extent the result of population incoherence, the effect is obvious in individual activity records. This damping effect, like that reported for *Drosophila*, is reversed by a period of bright light, as the model requires.

We first proposed that the systems had straight isochrons merely to make diagrams easy to draw and predictions correspondingly clear. Even so, in addition to the phenomena considered here, other features including phase resetting, steps up and down in light intensity and entrainment can be explained without seriously weakening this simplifying assumption. Our philosophy is thus to maintain this general framework until an obvious inconsistency appears.

The existence in *Culex* of activity rhythms in light suggests an obvious test of the model's consistency. Choosing any intensity one can select a phase marker, partition the state space into a new set of isochrons corresponding to that intensity, and conduct release–assay experiments using this new isochron map as a reference frame. Test conditions can be any light intensity including darkness. The form of these new assay curves can be predicted from that of the old curves assuming constant angular motion. Such experiments are in progress.

We have considered here the dynamics of a single oscillator, although it is almost certain that circadian rhythms reflect the interaction between coupled oscillators. Nevertheless, as Pavlidis[7] argues, preserving this duality in the description of circadian rhythms is useful and leads to no important contradiction.

We thank Dr B. C. Goodwin for helpful suggestions and criticisms of the manuscript. The work was supported by grants from the MRC.

Relative 'trophic' influences of excitatory and inhibitory innervation of locust skeletal muscle fibres

DENERVATION of locust skeletal muscle, where L-glutamate is thought to be the excitatory neurotransmitter[1], induces a pattern of physiological and pharmacological changes similar to that following denervation of vertebrate skeletal muscle[2,3]. The degeneration of nerve terminals on locust muscle which follows axotomy[4] is accompanied by a significant increase in the sensitivity of the extrajunctional membrane to L-glutamate[5–8], as well as a fall in resting membrane potential[8,9] and input conductance[8] of the denervated fibres. Locust skeletal muscle fibres are multiterminally and sometimes polyneuronally innervated. In addition to excitatory inputs some fibres receive endings from inhibitory axons in which transmission is probably mediated by γ-aminobutyric acid (GABA)[10]. This dual nervous control at the

peripheral level allows examination of the separate 'trophic' influences of excitatory and inhibitory inputs to a muscle fibre. In this report we demonstrate that in at least one locust muscle, the metathoracic retractor unguis (RU) of *Schistocerca gregaria* which contains fibres receiving both excitatory and inhibitory inputs, denervation-induced changes can occur in the presence of functionally intact inhibitory innervation.

The femoral portion of the RU muscle consists of two bundles of long (1 cm) fibres, called 'red' and 'white', usually containing eight and nine fibres, respectively[4,11]. Each bundle of fibres is innervated by one of a pair of large ('fast') excitatory motor axons which run in a branch (B_2) (ref. 4) of metathoracic nerve 5 (Fig. 1). Previous studies have suggested that the innervation of the RU is restricted to excitatory neurones; however, antidromic stimulation of $5B_2$ (distal to the point where it sends a process to the RU muscle to avoid stimulation of the excitatory inputs to this muscle) as well as metathoracic nerves 3 and 4 (see Fig. 1) usually evoked either a small depolarisation or hyperpolarisation in the red but not in the white fibres (Fig. 1) (C. Walther, personal communication). The properties of this response were identical to those of inhibitory postsynaptic potentials (i.p.s.ps) found in other locust muscles[10]: for example, it was reversibly abolished in Cl-free saline, and it had a reversal potential within a few millivolts of the resting potential (−50 to −60 mV in 10 mM K, locust saline[10]) (Fig. 1). Although i.p.s.ps could sometimes be seen in red fibres only when the membrane potential was displaced by ±5 mV, they were never recorded from white fibres even when the membrane potential was altered by ±15 mV.

Topically applied GABA (10^{-4}–10^{-3} M) caused ~50% reduction in the input resistance of the red fibres and also abolished the i.p.s.ps. Picrotoxin (5×10^{-4} to 10^{-3} M) reversibly abolished the i.p.s.ps and blocked the change in input resistance caused by GABA. Responses to GABA ejected iontophoretically from one barrel of a double-barrelled micropipette could be obtained from those regions in the clefts between fibres where a large, fast-rising depolarisation to glutamate was obtained from the second barrel, but not from extrajunctional areas where the glutamate sensitivity was very low. The reversal potential of the GABA response was similar to that of the i.p.s.ps. Bath application of GABA caused a significant change in input resistance of some of the white fibres, suggesting that perhaps these fibres receive an inhibitory input, although i.p.s.ps were not recorded from them.

In part of this study the RU muscle was denervated by sectioning metathoracic nerve 5 using an aseptic procedure[9]. It is possible that, like the RU excitatory axons, the inhibitory innervation to this muscle runs in metathoracic nerve 5, although it probably supplies other muscle fibres in the leg in addition to those of the RU. The RU on one side of each animal was denervated; the contralateral muscle was left unoperated to serve as a control. Operated animals were maintained in separate containers at 30 °C and fed fresh grass daily. Severing nerve 5 interrupts both the excitatory and inhibitory inputs to the RU simultaneously, and it is not feasible to section selectively excitatory and inhibitory axons. To selectively remove the excitatory inputs to the muscle, we have developed a procedure which leaves the inhibitory innervation of the RU muscle intact while deleting the excitatory input to this muscle. The procedure involved surgically excising that part of the metathoracic ganglion which contains the cell bodies of the RU excitatory motoneurones (Fig. 1*a*), but metathoracic nerve 5 was not sectioned. Animals operated in this way survived well for up to 4 weeks, which was the longest period studied.

Excitatory motor nerve terminal degeneration was complete 2–3 d after section of nerve 5, as judged by the absence of spontaneous miniature excitatory postsynaptic potentials and lack of response of the RU muscle to stimulation of the distal stump of nerve 5 (ref. 12). The sensitivity of the extrajunctional muscle membrane to L-glutamate applied iontophoretically through high-resistance (100–200 MΩ, 0.1 M Na-glutamate, *p*H 8) micropipettes was examined at various times up to 36 d after section of nerve 5 (and sometimes also nerve 3). The extrajunctional glutamate sensitivity increased significantly compared to control levels 4–6 d after nerve section, and reached a peak after 12–15 d, when the extrajunctional glutamate sensitivity was about 30 times greater than that of control muscles. The increase in extrajunctional sensitivity was accompanied by a decline in membrane potential and an increase in the input resistance of the muscle fibres[13]. These changes were similar in the red and white fibres. Animals with operated ganglia were examined 14 or more days post-operatively. By this time excitatory innervation had degenerated and the extrajunctional membrane of the RU muscle exhibited a high

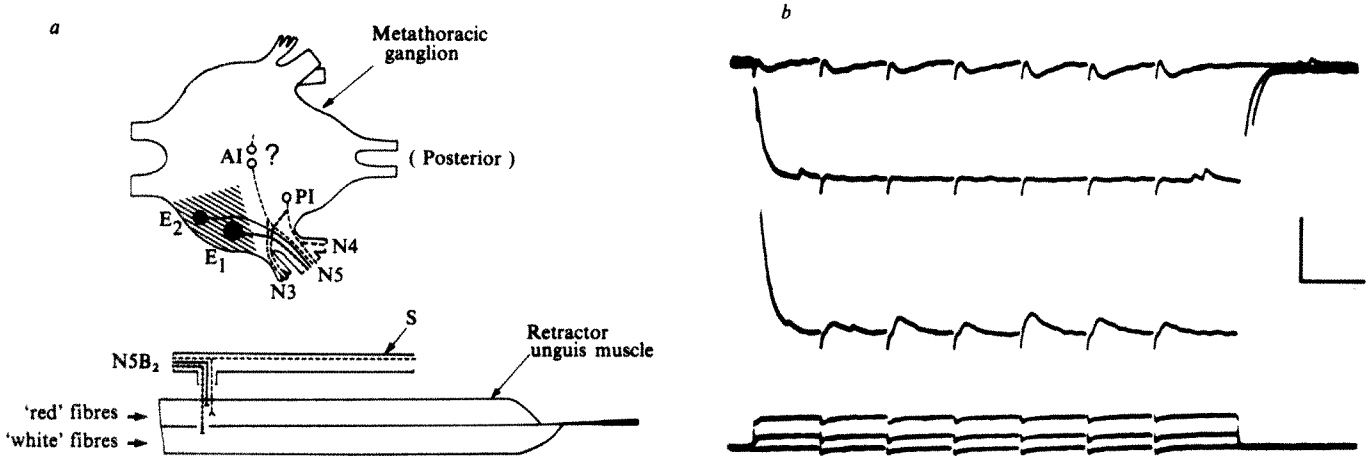

Fig. 1 *a*, Schematic diagram of the innervation of the femoral portion of the metathoracic retractor unguis (RU) muscle of *Schistocerca gregaria*. Each of the bundles of fibres ('red' and 'white') are innervated by one or two excitatory motoneurones in the metathoracic ganglion (E_1, E_2). The red fibres are also innervated by one or more inhibitory motoneurones, possibly branches of the anterior (AI) and posterior (PI) inhibitors which innervate the flexor tibiae (FT) muscle. The approximate positions of the cell bodies of E_1, E_2, AI and PI are shown (see refs 15 and 16 for details). Axons of both excitatory motoneurones run in metathoracic nerve 5, while axons of inhibitory motoneurones run in nerves 3, 4 and 5. The exact location of the inhibitory axons is not yet clear, and they are represented schematically. In some experiments the shaded part of the metathoracic ganglion was excised to delete selectively the excitatory innervation of the RU muscle. *b*, Intracellularly recorded inhibitory postsynaptic potentials (i.p.s.ps), evoked in a red fibre of the RU muscle by antidromic stimulation of branch B_2 of nerve 5 (S, in *a*). This nerve branch also innervates the FT muscle of the metathoracic leg. In this muscle fibre the i.p.s.ps were hyperpolarising at the resting potential, −54 mV. The membrane potential (upper traces) was altered by current injected through a second intracellular microelectrode (lower traces). Note that the i.p.s.ps disappeared when the membrane potential was hyperpolarised to −57 mV. Further hyperpolarisation reversed the polarity of the i.p.s.ps. Membrane potential, 2 mV; current, 20 nA; time, 100 ms. I.p.s.ps could also be recorded in RU fibres by antidromic stimulation of the inhibitory motoneurones through the axons which run in metathoracic nerves 3 and 4.

sensitivity to L-glutamate, similar to that of nerve-sectioned animals.

An example of the increased extrajunctional glutamate sensitivity which occurred on red fibres of denervated RU muscle is shown in Fig. 2. The excitatory innervation of the fibre had degenerated, but i.p.s.ps similar to those recorded from control fibres were recorded from the denervated fibre (Fig. 2). Qualitatively similar results were obtained from red fibres of muscles up to 18 d after nerve section, indicating that up to this time the inhibitory endings on these fibres were still capable of storing and releasing transmitter despite the fact that the axons had been sectioned. Similar results were obtained from animals with an operated ganglion, but in these cases not only could i.p.s.ps be recorded in red fibres on antidromic stimulation of $N5B_2$, but also during 'spontaneous' and 'reflex' activity of the inhibitory innervation and by stimulation of the inhibitory neurones through metathoracic nerves 3 and 4, indicating that the inhibitory inputs to the RU muscle were intact despite the disappearance of the excitatory innervation.

After periods of more than 21 d after section of nerve 5, i.p.s.ps were absent from all red fibres examined, suggesting that the inhibitory terminals had degenerated, although we have no structural evidence to support this conclusion at present. Electron microscope studies[4] of the branches of nerve trunk $5B_2$ which innervate the RU reveal that the excitatory axons are about 8–10 μm in diameter, whereas other axons in the branch, one or more of which are presumably inhibitory, are about 1 μm in diameter. The disappearance of the excitatory innervation 2–3 weeks before the disappearance of the inhibitory is probably due to more rapid degeneration of the large excitatory axons compared with the small inhibitory axons[4].

These experiments demonstrate that in red fibres of locust RU muscles, changes in properties resulting from degeneration of excitatory innervation, for example increased extrajunctional L-glutamate sensitivity, decline in membrane potential and increase in membrane resistance, can occur in the presence of a functionally intact inhibitory innervation. It is possible that trophic influences exerted over the red RU fibres by the inhibitory innervation may be relatively weak and nonspecific, as the inhibitory neurone which innervates the RU muscle probably innervates fibres of other muscles in the leg (for example flexor tibiae). In the case of the nerve section experiments any trophic influences exerted by the inhibitory innervation may be rapidly lost after section of nerve 5. The fact that mechanisms responsible for the production and release of inhibitory transmitter apparently remain intact up to about 3 weeks after nerve section gives little information about trophic factors associated with the inhibitory innervation which may be independent of the inhibitory transmitter. For example, trophic materials could be synthesised in the inhibitory neurone(s) and transported to the junctions by a fast component of axonal flow[14]. Following nerve section stores of such materials in the distal stump of the inhibitory axons would be rapidly depleted, although the nerve terminals could remain functional in a synaptic transmission sense for some time. However, these objections should not apply to the ganglion operation experiments, where the inhibitory innervation presumably remained intact.

One major difference between the excitatory and inhibitory inputs to the RU muscle lies in the ionic currents gated by the respective neurotransmitters. Whereas i.p.s.ps are generated exclusively by an increase in membrane permeability to Cl, the excitatory transmitter (probably L-glutamate) mediates an inward current of Na and Ca ions[17]. In view of the recent findings of Betz and Changeux[18] which suggest that Ca ions, together with cyclic nucleotides, may be important trophic factors in controlling the density of extrajunctional acetycholine receptors on vertebrate muscle, it is tempting to speculate that the changes in RU muscle properties that result from deletion of the excitatory inputs to the muscle arise indirectly from elimination of the influx of Ca ions into the muscle fibres which accompanies excitatory activity at the nerve–muscle junctions. The Ca ion influx would also be absent even if the inhibitory innervation to

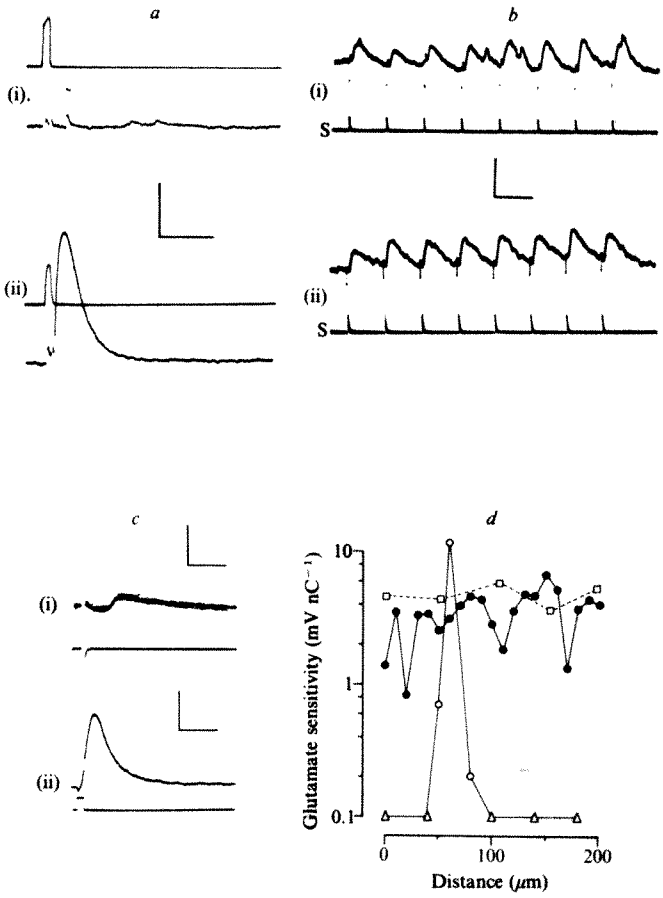

Fig. 2 *a*, Effect of denervation on the L-glutamate sensitivity of RU muscle fibres. (i) A dose of 2 nC (upper trace) applied to the extrajunctional membrane of an innervated control fibre failed to elicit a detectable response (lower trace). (Small responses were elicited with much higher doses of glutamate.) Note miniature excitatory postsynaptic potentials (min. e.p.s.ps). Resting potential of the fibre was −53 mV. (ii) A similar dose of glutamate applied to the extrajunctional membrane of a 'red' fibre of the muscle 16 d after nerve section evoked a large depolarisation. Note absence of min. e.p.s.ps. Resting potential of this fibre was −44 mV. Vertical and horizontal calibration bars, 2 mV, 100 ms, respectively. *b*, (i) I.p.s.ps recorded at the resting potential from the same control fibre as in (*a*). (ii). I.p.s.ps very similar to those recorded from the control fibre were recorded from the denervated fibre on stimulation of nerve $5B_2$ (see Fig. 1). Calibration bars, 0.5 mV, 100 ms, respectively. *c*, (i) Superimposed i.p.s.ps recorded from an RU muscle fibre of an animal 18 d after surgical deletion of the RU excitatory motoneurones. Resting potential of the fibre was −46 mV. These i.p.s.ps were recorded on stimulation of nerve $5B_2$, but similar responses were obtained on stimulation of metathoracic nerves 3 and 4. Calibration bars, 1 mV, 20 ms, respectively. (ii) Response to a 1-nC dose of glutamate (bottom trace) applied to the extrajunctional membrane of the same muscle fibre. Note that the excitatory innervation of the muscle had degenerated, that is no min. e.p.s.ps were observed on this or any other record from this fibre and e.p.s.ps. could not be evoked from the RU muscle fibres during stimulation of metathoracic nerve 5. Calibration bars, 2 mV, 200 ms, respectively. *d*, Comparison of the distribution of glutamate sensitivity of an innervated (Δ, ○) and a denervated (●) RU muscle fibre. The glutamate electrode was moved in 10–20-μm steps along the surface of the muscle fibre and the sensitivity to glutamate at each point measured in terms of the peak depolarisation produced by a 2-nC dose of glutamate. The sensitivity of the innervated fibre was less than 0.1 mV nC^{-1} (Δ) at most points on the fibre; the localised area of high sensitivity (○) corresponds to a neuromuscular junction. By contrast, extrajunctional membrane of the denervated fibre (16 d after section of nerve 5) had a large and nearly uniformly distributed glutamate sensitivity although not as high as that of former junctional sites (not shown). (□), Illustrates the extrajunctional glutamate sensitivity of an RU muscle fibre 16 d after deletion of the excitatory motoneurones.

the muscle remained intact, as Ca ions do not contribute to the inhibitory currents.

Further studies are in progress to evaluate the effect of selective deletion of inhibitory innervation on the properties of RU muscle.

Differential labelling of retinal neurones by ^{3}H-2-deoxyglucose

THE delineation of structural and functional interconnections in the vertebrate retina has long been a central problem in vision research. The Golgi technique[1,2], combined with ultrastructural studies[3,4] and post-recording injection of intracellular stains[5,6], has revealed the morphological and physiological properties of many of the individual cell types of the retina. Recently, light and electron microscope autoradiography with putative neurotransmitters has tentatively identified certain retinal neurones with specific transmitters[7,8]. However, very few techniques exist which can reveal the interconnections of a 'pathway' of retinal neurones in a functionally dependent manner. Radioactive 2-deoxyglucose (2-DG) is commonly used as a tracer in the central nervous system, where biochemical and autoradiographic studies have shown it to be a good indicator of local functional activity[9–11]. Transport and phosphorylation of 2-DG are identical to those of glucose, but no further metabolism beyond 2-DG-6-PO_4 occurs[12]. Most published studies using 2-DG as a tracer have used the ^{14}C-labelled form and frozen thick-sectioned tissue, a combination in which the resolution of morphological structure is unacceptable for studying neuronal connections in the retina. In the studies reported here, we have used tritium-labelled 2-DG in combination with plastic embedding to produce stimulus-dependent labelling at the cellular level in the isolated goldfish retina; our results suggest that these modifications of the '2-deoxyglucose technique' are useful for studying the physiology and functional connections of retinal neurones.

We chose the retina of the goldfish (*Carassius auratus*) for these studies because of its well characterised morphology and physiology[1,3–6]. After overnight dark-adaptation, goldfish eyecups were removed using an IR image converter. Small pieces of isolated retinas were removed from the eyecups under the same illumination as was used during incubation. For dark incubation, only IR illumination was used. Retinas were incubated in 0.2–0.5 ml of teleost Ringer's solution containing 100 mM NaCl, 3.5 mM KCl, 1.5 mM $MgCl_2$, 0.2 mM NaH_2PO_4, 30 mM $NaHCO_3$, 1.4 mM $CaCl_2$ and 2 mM glucose, *p*H 7.3, which had been presaturated with 95% O_2/5% CO_2. 2-Deoxy-D-[1-^{3}H]glucose (Amersham, TRK 383) was present at 1 mCi ml^{-1}.

Incubations were carried out in small vials sealed with cover slips and centred under the photostimulator beam. During incubation, retinas were maintained in the dark or stimulated with flashing broad-band white light or narrow-band red light of equal quanta. Stimulation was provided by a 6-V tungsten source with a maximum output of 300 μW cm^{-2}. The source gave a 22-mm diameter beam of collimated light. Neutral density filters were used to attenuate the light to 2×10^{12} quanta s^{-1} cm^{-2}, calculated at 550 nm (average 400–700 nm) for broad-band white light and isolated at 700 nm with an interference filter having a 13-nm half-peak bandwidth. This stimulus was delivered as a 1-Hz, 50% duty cycle square wave through the use of a rotating disk. After 20 min, an equal volume of double-strength fixative was added to the incubation mixture and stimulation continued for an additional 15 min. The pieces were

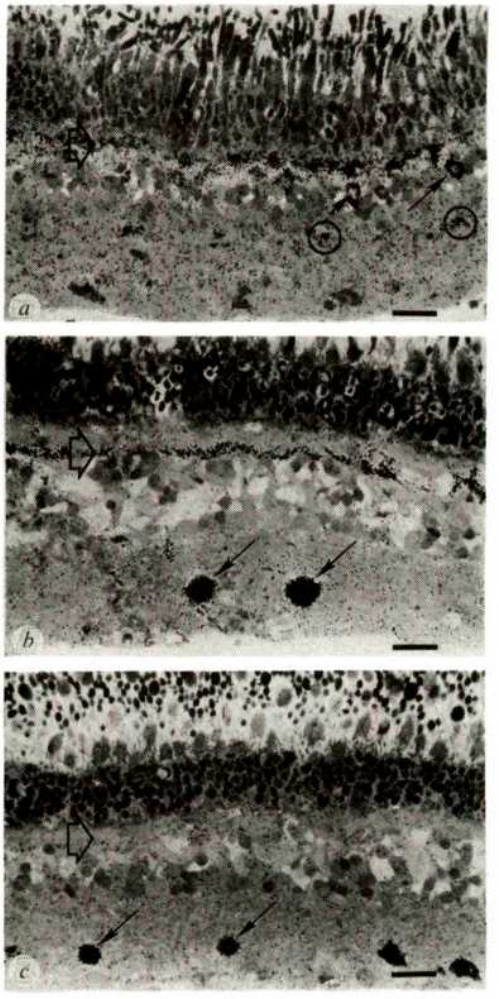

Fig. 1 Light microscope autoradiographs of isolated goldfish retinas incubated for 20 min in teleost Ringer's solution containing 1 mCi ml^{-1} ^{3}H-2-DG. *a*, Incubated in darkness after IR dissection. Label appears predominantly in photoreceptors, H1 horizontal cells (open arrow) and presumptive type *a* (centre-hyperpolarising) bipolar cells (closed arrows). The heavily labelled areas just beneath these cells, in sublamina *a* of the inner plexiform layer, are probably their axon terminals (open circles). *b*, Incubated under flashing narrow-band red light (700 nm) at 2×10^{12} quanta s^{-1} cm^{-2}. Label appears in H2 and/or H3 horizontal cells (open arrow) and type *b* (centre-depolarising) bipolar cell axon terminals (closed arrows). *c*, Incubated under flashing broad-band white light at 2×10^{12} quanta s^{-1} cm^{-2}. Very little label is seen in photoreceptors and horizontal cell layers (open arrow); only type *b* bipolar cell axon terminals are heavily labelled (closed arrows). Scale bars, 20 μm.

transferred to fresh 3% glutaraldehyde for 1–2 h, then rinsed twice for 10 min in 0.1 M phosphate buffer, *p*H 7.3, post-fixed for 1 h in buffered 1% OsO_4, rinsed twice for 10 min in buffer, dehydrated in graded ethanol and acetone, then embedded in Epon–araldite and polymerised for 48 h at 65 °C. Longitudinal and tangential sections of 1 μm were transferred to glass slides, coated with Kodak NTB2 emulsion and exposed at 4 °C for 2–3 weeks. After exposure, the slides were developed in Dektol for 2 min at 17 °C, washed, then stained with 1% toluidine blue. Similar retinas which were not embedded in plastic, but were extracted and analysed by paper chromatography[13], revealed that more than 85% of the tracer was present as 2-DG-6-PO_4, the remainder being 2-DG.

One of the major aims of this study was to determine whether ^{3}H-2-DG-labelled retinas embedded in plastic would provide resolution at the single cell level[14]. Figure 1 shows an autoradiograph from an experiment in which dark-adapted goldfish retinas were incubated with ^{3}H-2-DG in darkness (*a*), under flashing red light (700 nm) (*b*), and under flashing white light (*c*). This figure demonstrates that our modification of the 2-DG technique can be used to obtain resolution at the cellular level. Additionally, although we have not yet completed a detailed analysis of all the labelled cell types in these retinas, our preliminary analysis reveals several stimulation-dependent differences in the labelling patterns, possibly reflecting the functional dependence of ^{3}H-2-DG labelling. Dark-adapted retinas incubated in the dark with ^{3}H-2-DG (Fig. 1*a*) show considerable labelling in most rod and cone photoreceptors, heavy labelling in H1 horizontal cells (luminosity- or L-type) but not other horizontal cells, and heavy labelling in some presumptive type *a* (centre-hyperpolarising) but not type *b* (centre-depolarising) bipolar cells (terminology used is that of refs 4 and 6). Retinas incubated under flashing red light (Fig. 1*b*) show less labelling in photoreceptors, little labelling in H1 horizontal cells, but heavy labelling in H2 and/or H3 horizontal cells (chromaticity- or C-type) and in some type *b* bipolar cells. Retinas incubated under flashing white light (Fig. 1*c*) show almost no labelling in photoreceptors, only diffuse labelling in all horizontal cells, and heavy labelling in some type *b* bipolar cells. In all cases, very few amacrine or ganglion cells are labelled, possibly because the mode of stimulation was not optimal for labelling these cells.

In many cases, single 1-μm longitudinal sections through the retina were not very useful for identifying individual cell types. Accordingly, tangential and serial longitudinal sections were cut, prepared for autoradiography and exposed for longer periods of time. Figure 2 shows that these techniques permit the identification of specific cells in the retina. Tangential sections through the inner nuclear layer of the goldfish retina reveal the morphology of the horizontal cells which have taken up ^{3}H-2-DG. Figure 2*a* shows an H1 horizontal cell identified by this method, and for comparison, Fig. 2*b* shows an isolated H1 horizontal cell obtained by enzymatic dissociation[15]. Similar identifications can be made for other retinal neurones. To identify bipolar cells, autoradiograms of serial 1-μm longitudinal sections were traced in sequence and the tracings superimposed to demonstrate the cell's morphology (Fig. 2*c*). When these reconstructions are compared with isolated cells (Fig. 2*d*) or with cells impregnated by the Golgi technique (Fig. 2*e*) they can be readily identified as bipolar cells. In this particular case, the functional, positional and morphological characteristics reveal these cells to be type *b* bipolar cells[3–6]. The identification of the other labelled retinal neurones by these methods is now in progress. Thus, ^{3}H-2-DG incorporation under specific stimulus conditions can be used to demonstrate the functional morphology of certain retinal cell types.

Increased 2-DG labelling has been shown to reflect increased functional activity of neural tissue[16]. For retinal neurones, our autoradiographic results are consistent with the idea that accumulation is influenced by the membrane potentials of the cells, with depolarisation leading to enhanced labelling and hyperpolarisation to decreased labelling. The strongest evidence for this suggestion is the intense labelling of type *b* bipolar cells under red and white stimulation, conditions which are known to depolarise these cells. Further evidence lies in the increased labelling of H1 horizontal cells and presumptive type *a* bipolar cells in the dark, conditions in which they are depolarised; the H1 cells accumulate little label under red stimulation, a condition in which they are hyperpolarised. Thus, it seems that in all three incubation conditions, neurones in a depolarised state accumulate more label than those in a hyperpolarised state. This method may therefore be useful for the elucidation of neuronal connections and functional architecture in the retina, especially in retinas not easily amenable to intracellular recordings, as well as in other areas of the central nervous system.

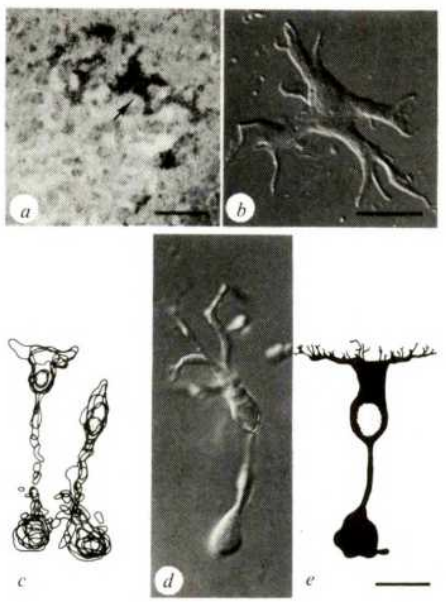

Fig. 2 Identification of ^{3}H-2-DG-labelled cells in the goldfish retina. *a*, Tangential section through the inner nuclear layer after dark incubation with ^{3}H-2-DG and subsequent autoradiographic preparation. An H1 horizontal cell is filled with label (arrow). Scale bar, 30 μm. *b*, For comparison, an isolated H1 horizontal cell prepared according to the dissociation technique of Lam[15]. Scale bar, 20 μm. *c*, Camera lucida tracings of serial longitudinal sections of a retina labelled under red light were superimposed to produce reconstructions of type *b* bipolar cells with axon terminals in sublamina *b* of the inner plexiform layer. Stippled areas identify the nuclei. *d*, An isolated type *b* bipolar cell prepared by cell dissociation. *e*, A type *b* bipolar cell impregnated by the Golgi technique (redrawn from Stell *et al.*[4]). Scale bar for *c*, *d* and *e*, 10 μm.

Glucocorticoids inhibit endorphin synthesis by pituitary cells

ENDORPHINS in the pituitary gland[1,2] are specifically localised in the intermediate and anterior lobes[3,4], whereas the posterior lobe contains much less opioid activity[4]. Recent results have indicated that β-endorphin and adrenocorticotropic hormone (ACTH) are synthesised by pituitary cells from a common precursor polypeptide[5–8] and that they both appear in the circulation after stressful stimulation[9]. It is well known that an increased potassium concentration stimulates the release of ACTH from pituitary cells in a calcium-dependent fashion[10]. Similar potassium-evoked release of endorphins was indicated in AtT/20 cells which originated in the anterior lobe of mouse pituitary tumours[11]. In addition, a basal release of endorphins was indicated, suggesting a possible dual regulation of endorphin secretion from the pituitary[11]. Coordinated release of ACTH, β-endorphin and β-lipotropin was reported[12] while the present study was in progress. This study was undertaken to determine whether glucocorticoid hormones, which are known to regulate ACTH, also regulate pituitary endorphins. Although it has recently been shown[9] that dexamethasone inhibits *in vivo* elevation of the content of pituitary endorphins after adrenalectomy, the mechanism of the action of this synthetic glucocorticoid remains unclear. Here, we describe data suggesting a direct inhibitory role of glucocorticoids in the synthesis of endorphins by pituitary cells.

The results shown in Fig. 1*a* indicate that the content of endorphins in AtT/20 pituitary cells was decreased when the cells were cultured with the synthetic glucocorticoids, dexamethasone and prednisolone. This effect is dose dependent and shows half-maximal response at 1.1±0.5 nM and 1.6± 0.6 nM for dexamethasone and prednisolone, respectively. The inhibitory role of the glucocorticoids was observed at these physiological concentrations only when the serum used for cell culture was extensively dialysed (Fig. 1). If non-dialysed serum was used, dexamethasone had significantly lower activity, decreasing the cellular content of endorphins by only 35±7% and 60±12% with 100 and 1,000 nM, respectively. These findings agree with previous studies which showed that the effect of steroids could be observed at physiological concentrations only after dialysis or charcoal absorbance, apparently through their removal of free steroids or some other form of inhibition.

As AtT/20 cells release endorphins spontaneously[11,12], we needed to know whether the decreased cellular endorphin content observed after treatment with prednisolone or dexamethasone reflected a shut-off of the synthesis of these peptides or whether the hormones caused the fall in the cellular levels by potentiating the release system. Therefore, the level of endorphins in the culture medium was also determined. Figure 1*b* shows that concomitantly with the drop in the cellular endorphin content seen with increasing concentrations of prednisolone or dexamethasone, there was a dose-dependent fall in the amount of endorphins in the culture medium. The effect of dexamethasone (10 nM) on the release of endorphins at different days after addition of the hormone showed a simple

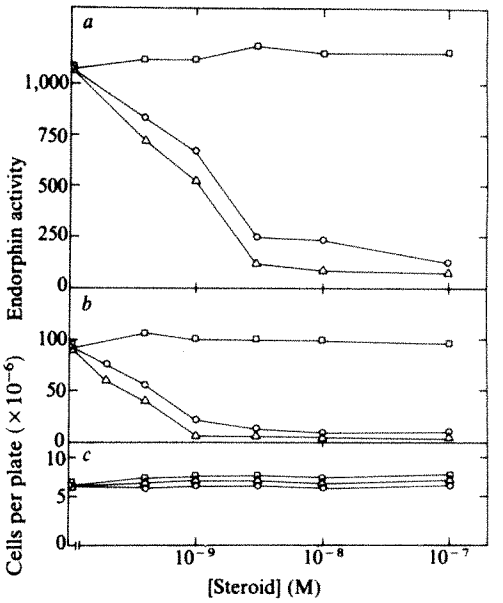

Fig. 1 Effect of steroid hormones on cellular and released endorphins from pituitary cells. AtT/20 mouse pituitary cells were cultured as described previously[11] except that the fetal calf serum (H-21, GIBCO) was extensively dialysed for 4 consecutive days against 50 volumes (each day) of 0.15 M NaCl. Cells were seeded for the experiments at 5×10^5 cells in 5 ml of culture medium containing 10% dialysed serum in a 60-mm Petri dish (Nunc). The cultures were treated on the day of inoculation and 48 h later with 5 μl of ethyl alcohol containing oestradiol benzoate (□), prednisolone (○) or dexamethasone (△) to give the indicated final hormone concentrations. Control dishes obtained 5 μl of ethyl alcohol. 48 h after the last hormone addition the cells were collected with the culture medium and the plates washed with 3 ml of phosphate-buffered saline, *p*H 7.4, which was added to the media containing the cells. This mixture was divided into two portions and centrifuged for 3 min in a low-speed centrifuge (500*g*). The medium of one portion was collected and stored at −20 °C and the cells were suspended in 0.1% EDTA in phosphate-buffered saline (PBS) and counted (C). The medium of the other portion was discarded and the cells were extracted in 3 ml of 0.1 M HCl. The homogenate was neutralised with 1/5 volume of 0.5 M Tris base, centrifuged for 10 min at 40,000*g* and the supernatant stored at −20 °C. Endorphin activity of the cell extracts (*a*) or the media (*b*) was quantitated by the opiate radioreceptor assay. We used this method rather than radioimmunoassay for quantitation of endorphins to ensure that all the endorphins were detected and also to avoid any possibility of misinterpretation due to cross-reaction between endorphin antibodies and other pituitary peptides. In these conditions, β-lipotropin was inactive. Rat brain tissue was used as the source of opiate receptors and details of the assay are described elsewhere[11]. Aliquots of 50–100 μl of the AtT/20 cell extracts or culture media were tested in duplicate and their activity was calculated from standard curves of Met-enkephalin (1–500 nM). Endorphin activity is expressed as pmol Met-enkephalin equivalents per 10^6 cells. Data presented are the average of three experiments carried out with duplicate plates for each hormone treatment.

time-dependent drop with no indication of any increases (data not shown). It was possible that the decreased endorphin levels in the presence of the glucocorticoids were a result of inhibition or other modification in cell proliferation. However, this was ruled out because (1) cells of each plate were counted and the cellular as well as the released endorphins were calculated per cell, and (2) there were no significant changes in cell multiplication after treatment with 0.2–100 nM prednisolone or dexamethasone (Fig. 1*c*).

The specificity of the effect of the steroids on AtT/20 cell endorphin content was also studied. Figure 1 indicates that 0.4–100 nM of Oestradiol benzoate had no significant effect on either the cellular content or the amounts of endorphins released. Two other sex hormones, progesterone and testosterone, and two other steroids, 17-α-epitestosterone and Δ^4-androsten-11β-3,17-dione, had no effect at 10 and 100 nM (Table 1). The specificity of the effect of the glucocorticoids was further indicated by the fact that incorporation of radiolabelled ^{3}H-dexamethasone into the nuclei of AtT cells was selectively inhibited by dexamethasone or prednisolone at nanomolar

0028-0836/79/340684—02$01.00

concentrations. In the same conditions, oestradiol benzoate, testosterone, 17-α-epitestosterone and Δ^4-androsten-11β-3,17-dione at 10 or 100 nM did not inhibit ^{3}H-dexamethasone incorporation by these cells (Table 1).

The inhibitory role of adrenal glucocorticoids on ACTH secretion seems to be mediated both by inhibition of the release of hypothalamic corticotropin-releasing factors and by a direct effect on the pituitary cells (ref. 13 and refs therein). The present study suggests that adrenal glucocorticoids at physiological concentrations inhibit endorphin synthesis by anterior pituitary AtT/20 cells in cultures that lack added hypothalamic factors. A previous study with AtT/20 cells[12] suggested that dexamethasone inhibits the stimulatory effect of hypothalamic factors which cause an increased release of endorphins. However, as the cells were cultured for 48 h with a high dexamethasone concentration (1,000 nM), one should reconsider the possibility that dexamethasone acted by decreasing the cellular endorphin content. This is supported by studies which indicated a concomitant decrease of cellular content and the basal release of ACTH after treatment of AtT cells with dexamethasone[14].

Recently, we have observed fluctuations in the content of pituitary endorphins during the normal oestrous cycle of female rats[15]. Interestingly, the lowest level of pituitary endorphins occurred at the day of proestrus, which was also found to be the day in which there was release of adrenal corticosterones[16]. It is conceivable, therefore, that physiological and experimental conditions that increase glucocorticoid levels in the blood can inhibit the synthesis of endorphins by pituitary cells and thereby decrease the amount of endorphins available for release to the peripheral circulation or other target tissues. Acute injection of morphine to experimental animals stimulates ACTH and adrenal hypersecretion. The fact that removal of the source of glucocorticoids in the body (by adrenalectomy) renders rats more susceptible to morphine is well known[17]. Thus, the possibility that glucocorticoid-induced suppression of endorphin synthesis in the pituitary gland may fulfil a role in chronically treated subjects deserves further study.

Table 1 Specificity of the effect of various steroids on cellular content of endorphins and on incorporation of ^{3}H-dexamethasone to AtT/20 pituitary cells

Steroid	Concentration (nM)	Cellular endorphins	^{3}H-Dexamethasone incorporation (fmol per 10^7 cells)
None	—	1,043±165	28.4±4.6

Cellular endorphin content was determined as described in Fig. 1. Data are pmol Met-enkephalin equivalents per 10^6 cells. Studies of the incorporation of ^{3}H-dexamethasone (23 Ci mmol^{-1}, Radiochemical Centre) to nuclei of AtT/20 cells were carried out as described elsewhere[18], with minor modifications. Cells were dispersed with 0.1% EDTA in PBS, counted, washed with culture medium without serum and dispersed at 2×10^7 cells per ml of the same medium. The cells were then incubated for 40 min at 37°C in a humidified incubator with 4×10^{-8} M ^{3}H-dexamethasone with or without the indicated concentration of unlabelled steroids. Nuclei were prepared and radioactivity was determined[18]. 10 μM dexamethasone was taken as the baseline of maximal displacement. All data are the average ±s.e. of duplicate samples from 2–4 experiments carried out independently. NT, Not tested.

*$P<0.001$; †$P<0.01$ compared with control samples.

Continuous culture of T cells cytotoxic for autologous human leukaemia cells

CYTOTOXIC T lymphocytes (CTLs), capable of lysing autologous and HLA-identical human leukaemia cells, can be generated *in vitro* by culturing lymphocytes from patients in remission from leukaemia with X-ray irradiated autologous leukaemia cells and irradiated allogeneic normal cells in 'three-cell' mixed leukocyte culture (MLC) protocols[1–3]. Additionally, T cells cultured with X-ray irradiated normal lymphocytes pooled from 20 unrelated individuals can differentiate into CTLs capable of lysing autologous Epstein–Barr (EB) virus-transformed lymphoblastoid cell lines and autologous human leukaemia cells, but not autologous normal cells[4,5]. Because *in vitro* generated CTLs directed against syngeneic tumour cells can inhibit tumour development in some animal tumour systems[6–9], it is likely that if large numbers of human CTLs cytotoxic for autologous malignant cells could be generated *in vitro*, these CTLs could be effective in eliminating residual malignant cells in patients who have received chemotherapy. Recent findings that normal human T cells[10,11] and allosensitised mouse[12] and human CTLs[13,14] grow continuously in medium containing T-cell growth factor (TCGF) derived from supernatants of mitogen-stimulated lymphocytes, have raised the possibility that large numbers of *in vitro* generated CTLs cytotoxic for autologous human malignant cells could be propagated by growing CTLs in TCGF. We report here that *in vitro* generated CTLs cytotoxic for autologous lymphoblastoid cell lines (LCL) and human leukaemia cells can be increased in number by several millionfold by growth in TCGF and that the continuously growing CTLs are highly cytotoxic for autologous abnormal cells.

Experiments were undertaken to determine whether large numbers of T cells cytotoxic for autologous EB virus-transformed LCL cells could be obtained by culturing T cells that had been sensitised to pooled allogeneic normal cells (pool$_x$) in TCGF. T lymphocytes stimulated with the 'pool' for 7 days lysed autologous LCL cells but not autologous normal cells; however, both the LCL cells and normal lymphocytes were lysed by pool-sensitised T cells from unrelated individual A (Table 1). After 27 days growth in TCGF, the CTLs had increased in number by nearly 10^7-fold; the resulting cells were at least threefold more cytotoxic for autologous LCL cells than were

T cells from the peripheral blood of normal individuals J, H and A were isolated by rosetting Ficoll–Hypaque purified mononuclear cells with sheep red blood cells (SRBC) by a method reported elsewhere[16] which was modified as follows. Briefly, 3 ml of 0.5% SRBC in phosphate-buffered saline (PBS) were mixed with an equal volume of mononuclear cells (5×10^6 cells ml^{-1}) and 0.6 ml heat-inactivated pooled human AB serum which had previously been adsorbed with SRBC as described previously[16]. The cell mixture was incubated at 37°C for 5 min, centrifuged at 50*g* for 5 min and incubated at 4 °C for 60 min. The cells were gently resuspended, layered on 10 ml of ice-cold Ficoll–Hypaque and centrifuged for 20 min at 400*g*. The pellet of rosetted cells was resuspended and SRBC were lysed by hypotonic shock. The T cells were washed with PBS and 5×10^6 responding T cells were cultured with equal numbers of X-ray irradiated (2,500 R) allogeneic lymphocytes pooled from 20 normal individuals (designated pool$_x$) or with equal numbers of X-ray irradiated autologous normal lymphocytes (designated J$_x$ and H$_x$) in 50 ml Falcon tissue culture flasks containing 5 ml of RPMI-1640 medium supplemented with 25 mM HEPES buffer and 20% heat-inactivated normal human serum, as previously described[4]. On day 7 after the onset of MLC, some of the effector cells were seeded in 50 ml Falcon tissue culture flasks at 1×10^5 cells ml^{-1} in 10 ml RPMI-1640 medium supplemented with 25 mM HEPES buffer, 20% heat-inactivated normal human serum and 10% TCGF (Associated Biomedic Systems). Before use TCGF was concentrated fourfold against polyethylene glycol powder, dialysed against 10 volumes of serum-free medium and assayed for optimal concentration as described elsewhere[15]. When the cells reached a density of 8×10^5–1×10^6 cells ml^{-1} they were re-seeded at 1×10^5 cells ml^{-1}. On day 7 after the onset of MLC (before growth in TCGF) and 34 days after the onset of MLC (after 27 days growth in TCGF) the effector cells were washed extensively and tested for their ability to lyse ^{51}Cr-labelled autologous LCL cells and normal lymphocytes in 6 hr ^{51}Cr release assays as previously described[4]. The % specific ^{51}Cr released from target cells was calculated as follows

$$\frac{\text{c.p.m. test release} - \text{c.p.m. spontaneous release}}{\text{c.p.m. maximal release} - \text{c.p.m. spontaneous release}} \times 100$$

where spontaneous release = c.p.m. released from target cells in medium alone and maximal release = c.p.m. released from target cells in detergent.

CTLs 7 days after pool sensitisation. Non-sensitised T cells from individuals J and H, following 27 days growth in TCGF, mediated low levels of cytotoxicity against autologous LCL cells.

Similar experiments to propagate CTLs cytotoxic for autologous leukaemia cells (Fig. 1) indicate that 7 days after pool sensitisation, T cells from a patient with hairy cell leukaemia mediated 27% specific ^{51}Cr release from the autologous leukaemia cells; after 26 days growth in TCGF 80% lysis of autologous leukaemia cells occurred whereas the patient's non-sensitised T cells grown in TCGF for the same length of time caused only 9.5% specific ^{51}Cr release. Normal autologous lymphocytes were not lysed by pool-sensitised T cells before or after growth in TCGF. In this and other experiments, CTLs grown for 3–5 weeks in TCGF were 3–4.5-fold more cytotoxic for autologous leukaemia cells than were CTLs 7 days after pool sensitisation. These findings are consistent with previous reports that mouse CTLs directed against syngeneic leukaemia cells are more cytotoxic after growth in TCGF[12,15].

With some leukaemia patients we have failed to detect cytotoxicity against autologous leukaemia cells after pool sensitisation, or after sensitisation in three-cell protocols with autologous leukaemia cells and allogeneic normal cells. In at least some of these cases, it is possible that CTLs are generated against the autologous leukaemia cells but that the level of cytotoxicity is below that detectable by our assay. We thus investigated whether growth of 'sensitised' cells in TCGF in such cases would result in detection of anti-leukaemic CTLs, as sensitised cells grown in TCGF are more cytotoxic than CTLs 7 days after sensitisation. T cells from a patient in relapse with acute myelogenous leukaemia mediated no cytotoxicity against autologous leukaemia cells on day 7 after sensitisation with the pool or after sensitisation in the three-cell protocol (Table 2a). In contrast, after the sensitised cells had been grown for 11 days in TCGF, the effector cells were highly cytotoxic. When, later, with the patient in remission, T cells were isolated and subjected to pool sensitisation or sensitisation in the three-cell protocol, once again no cytotoxicity was detected on the leukaemia cells (Table 2*b*). However, after 19 days of growth in TCGF, high levels of cytotoxicity were detected against autologous leukaemia cells but not against autologous remission bone marrow cells which were, however, lysed by pool-sensitised T cells from unrelated individual N.

That lysis of autologous LCL and leukaemia cells by sensitised lymphocytes following growth in TCGF is mediated by CTLs rather than allo- or TCGF-activated natural killer (NK) cells is supported by the following findings. First, 92–95% of the effector cells grown in TCGF formed rosettes with sheep red blood cells (SRBC). Second, NK cells express receptors for the Fc portion of IgG and can be removed by adsorption to SRBC monolayers coated with anti-SRBC IgG[17,18]. Nonsensitised and pool-sensitised human lymphocytes cultured in fetal calf serum are markedly cytotoxic for NK-sensitive target cells and most of this cytotoxic activity can be removed by depletion of Fc receptor-bearing cells (ref. 19 and J.M.Z., unpublished observations). In contrast, we have found that depletion of Fc receptor-bearing cells from pool-sensitised cells generated in human serum does not reduce cytotoxicity for allogeneic NK-sensitive targets or autologous abnormal cells[18]. Third, we wondered whether leukaemia cells would be lysed by autologous NK cells activated by interferon. Although interferon treatment augments NK-cell activity against allogeneic NK-sensitive leukaemia cells[18,20], cells treated with interferon were not cytotoxic for autologous leukaemia cells (J.M.Z., unpublished observations), indicating that even if TCGF can activate NK cells, the

Table 2 Lysis of autologous acute myelogenous leukaemia cells by *in vitro* sensitised T cells after growth in TCGF

Responding T cells	Stimulating cells	Days after sensitisation	Days grown in TCGF	Effector: target ratio	% Specific ^{51}Cr release ± s.d. Leukaemia cells	% Specific ^{51}Cr release ± s.d. Remission marrow cells

T cells were isolated as described in Table 1 from the peripheral blood of patient P who was in relapse (*a*) and remission (*b*) from acute myelogenous leukaemia. T cells (5×10^6) were cultured with 5×10^6 X-ray irradiated (4,000 R) autologous leukaemia cells (designated L_x) and 5×10^6 X-ray irradiated (2,500 R) allogeneic normal lymphocytes (designated A_x) or with 5×10^6 X-ray irradiated (2,500 R) allogeneic normal lymphocytes pooled from 20 unrelated individuals (designated $pool_x$) as described in Table 1. On day 7 after the onset of MLCs, the sensitised cells were collected and seeded in medium containing 10% TCGF, as described in Table 1. On day 7 after sensitisation and following growth in TCGF, the cells were tested for their ability to lyse ^{51}Cr-labelled autologous leukaemia cells and remission bone marrow cells in 6-hr ^{51}Cr-release assays as detailed in Table 1. The leukaemia cells and remission bone marrow cells, which had previously been control-rate frozen and stored in liquid nitrogen, were thawed and cultured in medium for 12 h before use as target cells. 92–94% of the patient's sensitized cells, after growth in TCGF, formed rosettes with SRBC.

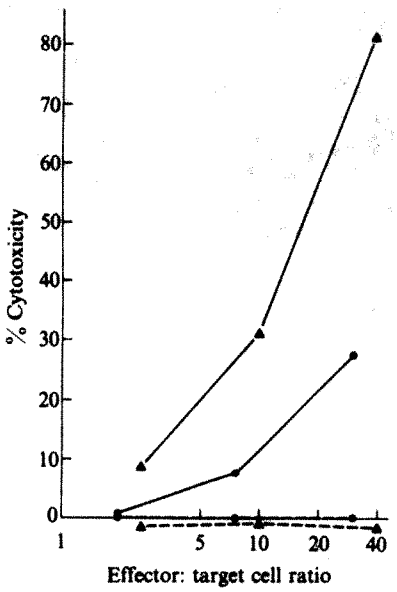

Fig. 1 Lysis of autologous hairy cell leukaemia cells (———) and autologous normal T lymphocytes (– – – –) by T cells sensitised for 7 days with X-ray irradiated pooled allogeneic normal cells before growth in TCGF (●) and after 26 days growth in TCGF (▲). The T cells were isolated, sensitised, grown in TCGF and assayed for cytotoxicity as described in Table 1. The leukaemia cells were isolated from the patient's spleen[5] and were control-rate frozen and stored in liquid nitrogen until 12 h before use as target cells, at which time they were thawed and cultured in medium. 93% of the pool-sensitised cells grown in TCGF formed rosettes with SRBC. Non-sensitised T cells, grown in TCGF for 26 days, mediated only 9.5% ^{51}Cr release from autologous leukaemia cells at an effector: target cell ratio of 40:1.

leukaemia cells do not seem to be susceptible to lysis by activated autologous NK cells.

The results presented here may be important for the following reasons. First, past studies aimed at generating CTLs *in vitro* against autologous or HLA-identical leukaemia cells have demonstrated that in some cases no cytotoxicity is detected following sensitisation[2,3,5]. Our finding that such sensitised T cells cultured in TCGF exhibit significant cytotoxicity for autologous leukaemia cells suggests that the leukaemia cells of at least some of these patients express target antigens against which autologous CTLs can be generated. This approach may also be useful in other systems in which CTLs may be stimulated but in numbers that cannot be detected before growth in TCGF. Second, for basic studies and possible immunotherapeutic application, it is desirable to have large numbers of T lymphocytes highly cytotoxic for autologous leukaemia cells. Growth of *in vitro* generated anti-leukaemic CTLs in TCGF would be a useful approach to this problem, as the number of CTLs can be increased at least 5×10^6 times by 3 weeks growth in TCGF. As continuous cultures of CTLs cytotoxic for syngeneic mouse leukaemia cells inhibit leukaemia development *in vivo*[21], it is possible that continuous cultures of human CTLs cytotoxic for autologous leukaemia cells may be of immunotherapeutic value in leukaemia patients.

We thank L. Eskra and R. Klopp for technical assistance and M. Howard and C. Smith for help in preparation of this manuscript. Thy-1 antigen on astrocytes in long-term cultures of rat central nervous system

THE THY-1 ANTIGEN has been exploited by immunologists as a marker for thymus-derived lymphocytes in mice[1]. Since its first description by Reif and Allen, it has been known to be present in equivalent amounts in brain and thymus[2]. However, in contrast to thymus, where adult levels of Thy-1 are present at birth, Thy-1 in mouse and rat brain increases with physiological maturation of the brain from 1–2% at birth to 100% of the adult level by 3–6 weeks of age[2–5]. It is widely assumed that neurones are the principal cell type which express Thy-1 and by implication that the increase in brain Thy-1 during neonatal development is related to increases in neuronal membrane as a result of dendritic arborisation[5]. I describe here the use of monoclonal anti-Thy-1 antiserum in combination with other recently defined neural cell markers[6] to study the distribution of Thy-1 on cells grown in long-term cultures of rat central nervous system. I have found that Thy-1 appears on astrocytes as well as neurones and fibroblasts but not on oligodendrocytes, and that the rate of appearance of Thy-1 on cultured astrocytes parallels that of Thy-1 in brain *in vivo*. This is the first report to identify unambiguously Thy-1 on astrocytes. It settles a controversial point about the Thy-1 distribution on neural cells and clearly demonstrates that previous implications (see discussion) that neurones are the major Thy-1-positive cells in the brain is incorrect.

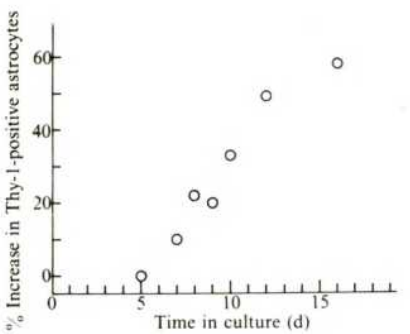

Fig. 1 Increase in percentage of Thy-1-positive astrocytes with time in culture. Cells from 5–6-d old rat corpus callosum were grown and studied by indirect immunofluorescence[6]. Data were collected from three separate experiments counting at least 150 GFAP-positive cells per coverslip.

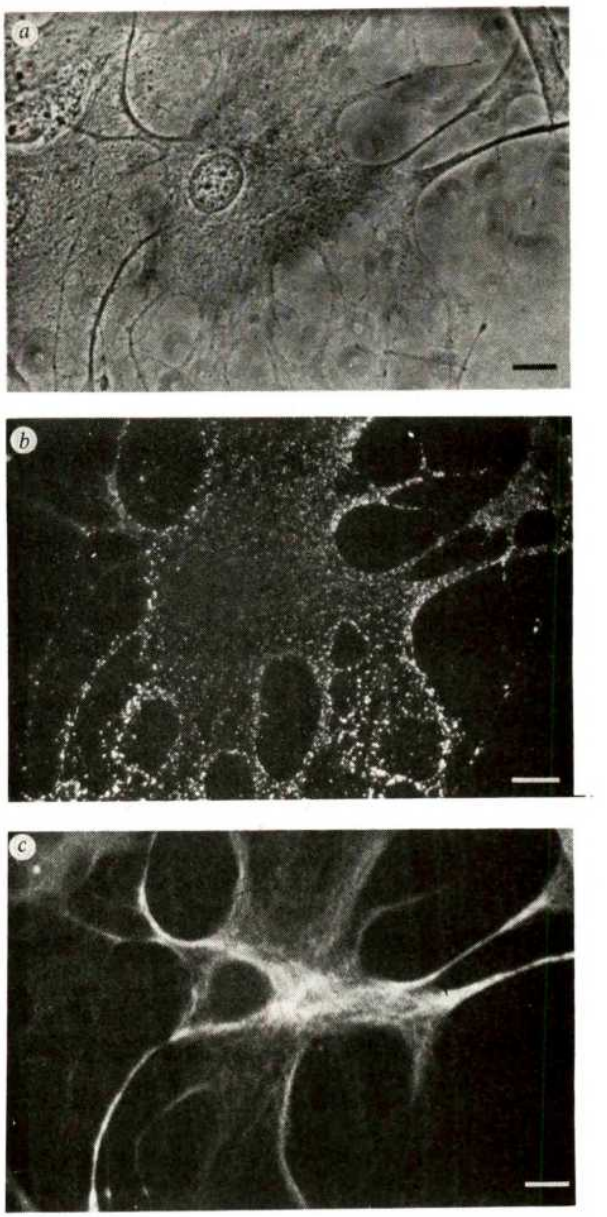

Fig. 2 Presence of Thy-1 on 'protoplasmic' astrocytes. Cells were labelled using mouse anti-Thy-1, followed by goat anti-mouse Ig–rhodamine, fixed, then labelled with rabbit anti-GFAP followed by goat anti-rabbit Ig–fluorescein[6] and viewed with phase contrast (*a*); rhodamine (*b*), or fluorescein optics (*c*). Scale bar, 10 μm.
